The principles enumerated are not only good but are long established. However, there is much room for discussion regarding the order in which Becker here mentions these principles. If the order of mention is to be that of relative importance, this will depend not only upon the training, viewpoint, and inclination of the physician, but also upon the particular constellation of circumstances bearing upon the particular case at the particular moment.

CLINICAL AND EXPERIMENTAL

THE EFFECT OF THE SUBCUTANEOUS ADMINISTRATION OF PROTAMINE (SALMINE) TO RABBITS AND MICE*

ILMARI VARTIAINEN, M.D., AND ALEXANDER MARBLE, M.D.
BOSTON, MASS.

FOLLOWING the announcement of Hagedorn¹ in 1935 that the addition of protamine greatly prolongs the action of insulin, this substance has been used widely as a constituent of protamine insulin and protamine zinc insulin. If used in small doses, protamine apparently has no deleterious effect upon the organism. However, since over a period of years many diabetic patients take relatively large quantities of insulin, the question has arisen as to how large amounts of protamine insulin can be given safely.

Forty years ago Thompson,² working in Kossel's³ laboratory, reported the results obtained when protamine was injected intravenously into ureotized dogs. He found that a dose of elupeine (originally regarded as chemically identical with salmine) greater than 15 to 18 mg. per kilogram could not be given without causing death of the animal. Following the injection of protamine a definite and relatively prompt fall of the blood pressure took place. After a nonfatal dose, the blood pressure regained the normal level in twenty-five to thirty minutes. Simultaneous with the fall in the blood pressure after a nonfatal dose, the respirations at first became increased in rate and depth; then followed a period of rest and finally gradual resumption of normal breathing. It was noteworthy, however, that active thoracic breathing was absent as long as the effect of the protamine lasted. In addition to the effects upon the blood pressure and the respiration, Thompson noted delayed clotting of the blood and a diminution in the number of circulating leucocytes.

Jappelli⁴ in 1933 repeated Thompson's experiments in unanesthetized animals. Doses of salmine of 20 mg. per kilogram of animal caused agitation, dyspnea, salivation, diarrhea, and a drop in the arterial blood pressure. A second dose caused a further drop in arterial pressure, and a third was fatal (vasomotor paralysis).

According to Walther and Ammon,⁵ three guinea pigs of 250 to 300 Gm. body weight survived two intraperitoneal injections each of 5 to 10 mg. of protamine. They died, however, following intraeardial injections of 35 mg. four weeks later.

*From the George F. Baker Clinic, Elliott P. Joslin, M.D., Medical Director, New England Deaconess Hospital, Boston.

Dr. Vartiainen was the holder of a fellowship of the Finnish Government.

Received for publication, April 24, 1940.

Because in the literature there are no data regarding the toxicity of protamine when given subcutaneously, we have determined the lethal dose for mice and rabbits and have studied the signs and symptoms which follow the administration of large amounts.

RESULTS

Lethal Doses.—The lethal dose following subcutaneous injection was determined in 40 mice and 23 rabbits.

Female mice weighing from 12.0 to 33.5 Gm. were used. Food and water were withheld during the first twelve hours after the administration of protamine, but were allowed before and after that time. The neutralized protamine* was given subcutaneously in 1 per cent concentration in a physiologic solution of sodium chloride. The behavior of the animals was observed for five days after the injections.

As may be seen in Table I, the average or median lethal dose of protamine in our experiments was about 250 mg. per kilogram of animal. All deaths occurred within one hour after injection.

TABLE I

MORTALITY OF MICE AFTER A SINGLE SUBCUTANEOUS INJECTION OF PROTAMINE (SALMINE)

DOSE PER KG. ANIMAL (MG.)	NUMBER OF MICE TESTED	NUMBER OF MICE DYING	TIME OF DEATH AFTER INJECTION (MIN.)
400	2	2	18-32
300	10	8	19-55
250	10	5	23-60
200	10	1	40
100	4	0	
50	2	0	
25	2	0	

TABLE II

MORTALITY OF RABBITS AFTER A SINGLE SUBCUTANEOUS INJECTION OF PROTAMINE (SALMINE)

DOSE PER KG. ANIMAL (MG.)	NUMBER OF RABBITS TESTED	NUMBER OF RABBITS DYING	TIME OF DEATH AFTER INJECTION (HR.)
500	2	2	4-10
300	8	3	8-16
200	5	3	5-12
100	4	0	
50	2	0	
25	2	0	

Male rabbits weighing 1,180 to 2,760 Gm. and fasted twenty-four hours were used. No food or water was allowed during the first twelve hours after injection of protamine. The behavior of the animals was observed during the following five days. The protamine was injected in 10 per cent concentration in a physiologic solution of sodium chloride. Before injection these preparations were warmed to about body temperature in order to diminish the turbidity which was present in the cold.

*The protamine used was salmine (Lot No. 961271) prepared by Eli Lilly & Co., Indianapolis, and furnished to us without cost.

The median lethal dose of salmine injected subcutaneously seemed to be essentially the same in rabbits as in mice (Table II), being between 200 and 300 mg. per kilogram of animal (a dose of 250 mg. per kilogram was not used with the rabbits). However, the results were not as uniform as in the mouse experiments; it is possible that this may have depended upon the more delayed and uneven absorption of protamine when injected in 10 per cent, rather than 1 per cent, concentration. In contrast with the experience with mice, only one of the rabbits died during the first four hours after an injection.

Signs and Symptoms Following the Subcutaneous Injection of Large Amounts of Protamine.—One of the most striking early signs noted following the subcutaneous injection of salmine was the dilatation of superficial blood vessels, as seen particularly in the ears of rabbits. This was first observed usually fifteen to twenty minutes after an injection and reached its maximal intensity thirty to ninety minutes after the injection. Although barely demonstrable after the smaller doses used (50 to 100 mg. per kilogram), it was marked after the larger doses. The large ears of white New Zealand rabbits became warm and strikingly bluish red.

Beginning with the third hour after injection, there appeared in some animals certain signs of blood vessel damage, especially after doses larger than 200 mg. per kilogram. Thus pressure upon the ear with the finger tips produced blanching which persisted for an unusually long time. The prominence of this feature depended somewhat upon the degree of dilatation of the superficial blood vessels at the time pressure was applied. In a few cases there was to be seen at about the fourth hour following injection a marked edema of the ears which remained visible the following day.

In most of the fatal cases the rabbits had marked respiratory distress, beginning one to two hours after the injection. Breathing became very labored and slower than normal. Sometimes râles could be heard, suggesting pulmonary edema. At this stage the animals often assumed a position of opisthotonos, with the nose lifted up and the ears directed along the back. At times this position was maintained by supporting the chin on a base, as on the edge of a basket or pan. After doses of 100 to 500 mg. per kilogram there sometimes occurred rigidity of the animal, which reached a maximum in the fifth to seventh hour after injection, and occasionally could still be seen the following day.

Following doses of from 50 mg. per kilogram and more, the animals seemed to suffer from marked malaise between the first to fifth hours and after large doses this persisted even longer.

Between the second and sixth hours many rabbits showed a definite increase in the output of urine; this was usually very light and clear. The urine occasionally reduced Benedict's solution but to no greater extent than did 0.15 per cent glucose. During a period in which rabbit P16 (dose of protamine, 200 mg. per kilogram) had marked hyperglycemia, no urine was obtained for sugar determinations. Rabbits P22 and P25 (dose of protamine, 300 and 200 mg. per kilogram, respectively), showing marked changes in the kidneys at post mortem, had in the urine albumin, granular casts, red blood corpuscles, white blood cells, and epithelial cells.

Chart 1.—Effect of the subcutaneous injection of protamine on the rectal temperature of rabbits. Animals P14 and P15 received 100 mg., and P16 and P17 200 mg., per kilogram of body weight. The sign + indicates death of the animal.

Chart 2.—Effect of the subcutaneous injection of protamine on the blood sugar of rabbits. Animals P14 and P15 received 100 mg., and P16 and P17 200 mg., per kilogram of body weight. The sign + indicates death of the animal.

One of the rabbits (P25) developed, after the fifth hour following injection, paralysis of left anterior and right posterior limbs.

Some of the animals showed between the first and third hour the frequent defeecation of a moist mucous fecal mass.

In a group of eight rabbits the changes in body temperature after the injection of protamine were studied by hourly rectal measurements. The largest doses used in these experiments, 200 mg. per kilogram, caused a marked fall of body temperature within two hours after the injection of protamine. After that, the temperature rose again, reaching levels above normal. Even the smaller doses (25 to 100 mg. per kilogram) had a similar effect, that of 25 mg. per kilogram being very slight.

The blood sugar, studied in the same eight rabbits, showed marked alterations (samples of 0.1 c.c. were taken from a marginal ear vein, and the sugar content was determined according to the method of Folin and Malmros⁶). During the first two hours the values were increased, showing a maximum usually at one hour after the injection of protamine. During a second rise, which began usually in the third hour, one of the animals (P16) had premortal values as high as 372 mg. per 100 c.c.

The symptoms in mice after injections of protamine corresponded to those in rabbits, although they were more difficult to follow accurately. After a dose of 200 to 400 mg. per kilogram of animal, all the surviving mice seemed very ill during the first one to five hours. Six animals were opisthotonic about ten to fifty minutes after the injection. Many mice had marked rigidity of the body about one hour after the injection. Some of the animals had clonic convulsions a short time before death; others died with the body flaccid.

After a dose of 50 to 100 mg. per kilogram of animal, the mice seemed to suffer malaise for a few hours. The smallest dose of 25 mg. per kilogram seemed to have no effect upon the animals.

*Post-mortem Findings.**—The most striking and constant finding on examination of the rabbits which died were hemorrhages in the thymus gland. These varied in extent from areas of pin-point size to massive involvement of the gland. The extent of the hemorrhages did not seem to depend absolutely upon the size of the dose of protamine used, although all animals dying had received relatively large amounts. The lungs showed many pleural and parenchymatous hemorrhages of varying size, and frequently there was bloody foam in the trachea and bronchi. The changes in the lungs seemed to parallel roughly in extent those in the thymus. The kidneys showed cortical and subcortical foci of hemorrhage and necrosis, suggesting infarcts, from pin-point size to 5 mm. In mice the most constant findings were in the lungs, which were edematous and often showed tiny points of hemorrhage on the surface. Hemorrhages were noted also on the surface of the thymus and adrenal glands.

Microscopic study of the tissues confirmed the findings made on gross examination. In addition, the liver showed some degree of focal necrosis with polymorphonuclear infiltration; in one instance the process was widespread with

*The necropsies reported in this paper were carried out immediately after the spontaneous death of the animals. Tissues were placed in formalin or Zenker's fluid.

involvement of about half of the liver tissue in the sections examined. Degeneration of the tubular epithelium of the kidney with many hyaline casts in the tubules was seen. In one rabbit a small area of focal necrosis with polymorphonuclear infiltration was seen in one adrenal gland.

DISCUSSION

The data presented in this paper demonstrate that protamine (salmine) is definitely toxic when given subcutaneously in large amounts. However, the doses required for the appearance of abnormal signs are relatively enormous.

A dose of protamine zinc insulin of 100 units is from two to three times as great as that used daily by a patient with diabetes of moderate severity. According to present standards, 1.25 mg. of protamine are contained in each 100 units of protamine zinc insulin. For a patient weighing 65 kg. this would represent roughly 0.02 mg. per kilogram, or about $\frac{1}{10,000}$ the minimal lethal dose as established in our work for mice and rabbits. Furthermore, the tendency to toxic effect probably is lessened because of the tolerance gradually set up by the daily subcutaneous administration. At any rate, in an extensive use of protamine-containing insulin in hundreds of cases of diabetes treated since 1935 at the George F. Baker Clinic, no harmful effects have been observed which could be attributed to the protamine per se. Local responses consisting of redness, swelling, heat, soreness, and itching at the site of injection are frequently seen, but even these effects usually become less and disappear after injections have been continued for several days or at the most, a few weeks.

Although we have regarded these local responses to protamine zinc insulin as allergic in nature, Kern and Langner⁷ doubt this because they obtained negative intracutaneous reactions with a protamine solution in 104 diabetic patients treated with protamine zinc insulin. They quote Taylor⁸ and Wells⁹ to the effect that protamines have no antigenic properties; furthermore, they were unable to induce sensitivity to protamine in four guinea pigs.

In an article already mentioned, Walther and Ammon⁵ interpret the death of three guinea pigs, each of which was given two parenteral injections of protamine four weeks apart, as due to anaphylactic shock. It is possible that the fatalities observed by Walther and Ammon occurred on a purely toxic, rather than an allergic, basis. Walther and Ammon gave as their second or "shocking" dose, 35 mg. of protamine to a guinea pig weighing 250 to 300 mg., or approximately 115 to 140 mg. per kilogram. Although this is somewhat below the median lethal dose which we found in mice and rabbits after subcutaneous administration, nevertheless, it is a large dose and may have been more effective, given as it was, intracardially.

The events which are observed to follow the injection of large amounts of protamine into rabbits and mice, together with the pathologic findings, probably are not specific, resembling in many respects those seen after the parenteral introduction of various foreign substances, including proteins. To some extent our findings resemble those observed by Selye¹⁰ following sublethal doses of various drugs, as histamine, adrenalin, atropine, morphine, and formaldehyde. The "alarm reaction" produced is considered by Selye to represent simply the response of the organism to a damaging stimulus.

SUMMARY

1. The effect of the subcutaneous administration of large amounts of protamine (salmine) to 40 mice and 23 rabbits was studied.

2. The median lethal dose was found to be about 200 to 300 mg. per kilogram body weight.

3. The symptoms and signs produced by the injection of protamine consisted of respiratory distress, muscular rigidity, and opisthotonos, marked malaise, polyuria, fall in body temperature followed by a rise, and hyperglycemia. Dilatation of superficial blood vessels with some evidence of damage was noted.

4. Post-mortem examination of animals dying as the result of an injection of protamine showed signs of vascular damage with hemorrhages into the thymus, lungs, and kidneys. Other findings included infarcts in the kidneys, acute toxic changes in the kidney tubules, and focal necrosis of the liver.

5. It is concluded that the amount of protamine contained in insulin used in the treatment of diabetes represents so small a fraction of that found harmful to rabbits and mice that the possibility of its being a hazard is remote.

PRELIMINARY OBSERVATIONS ON LOWERING OF BODY TEMPERATURES*

SAMUEL B. NUZIE, M.D., AND S. LEONARD NIZIE, B.A.
MATTOON, ILL.

WITH THE ASSISTANCE OF WILLIAM E. STIGERS

"PROFOUND oblivion midway between sleep and death" may be poetic eloquence, yet it expresses the intermediate stages of lethargy resulting from the associated efforts of sedation and refrigeration. The lowering of body temperature to approximately 20° F. in the dog by artificial means simulates natural hibernation in the upper strata of mammals.

The following report will endeavor to picture the physiological events occurring with metabolism at its apparently lowest ebb, and yet this ebb is compatible with life. To achieve this end, which others have suggested to be a palliative consideration for generalized cancer disease, a technique revolving around the simple idea of electrical refrigeration was employed.

In order to produce this lowered body temperature in a controlled manner, a cabinet cooled by electrical refrigeration was devised. This consisted of a rectangular wooden box insulated with several layers of cork. A swinging door, likewise insulated, was arranged to allow for free access to the interior, which measured 24 by 12 by 12 inches. The cabinet lay on its long side, facilitating such matters as laying the animal in a comfortable position and placing the necessary recording instruments. A metal shelf upon which the dog rested was set 6 inches from the floor of the cabinet, thus assuring sufficient byways and highways for the proper physics of refrigeration. From the ceiling of the box were suspended coils connected to the compressor, thereby completing the refrigerating system. In the ceiling and the floor were two one-inch vents, solving the problem of aeration for the animal. Emerging from the top of the cabinet, closely situated to the corners, were outlets just large enough to permit the exits of a 1/4 inch rubber tube for the intravenous anesthetic, a capillary tube from the rectal thermometer, a tube from the cabinet thermometer, a tube from the interior to the humidistat, a tube from the pneumograph to its manometer, a tube from the femoral artery to its pulsometer, and two metal tubes from the coils to the compressor unit.

Behind, and on the same stand with the cabinet, was placed the 1/4 H. P. compressor unit capable of 2,000 B.T.U.'s. Difluorodichloromethane was used for the refrigerant. This unit was capable of lowering the temperature of the interior of the cabinet (no animal) from 69° F. (room temperature) to 32° F. within eighty minutes.

*From the Mattoon Polyclinic, Mattoon
Received for publication, May 3, 1940.

Anesthesia of the dogs was produced and maintained by continuous intravenous gravity (drop) method with a 0.5 per cent solution of pentothal sodium. This was given in all cases.

The dogs used were very much alike in type, weighing about 15 pounds. For obvious reasons, they were chosen for their short hair.

Chart 1.—Body temperature and cabinet temperature.

The actual experiment was conducted in the following manner: First, a $\frac{1}{2}$ inch No. 18 needle was inserted into the right cephalic vein and connected to the adapter of the intravenous apparatus. Sixty drops per minute induced the animal within ten minutes to the stage of insensibility. The dog was then placed upon the metal shelf so that it lay on its right side with its feet pointing outward. The pneumograph was connected around the lowest part of the chest. The pulsograph was taped to the left femoral artery. The thermometer was inserted deeply into the rectum, the tail was allowed to drop down between its legs and fastened in this fashion to secure a permanent position of the rectal thermometer. Everything was in readiness for the actual cooling after a normal set of readings of the pulse, respiration, temperature of the animal, temperature of the room, and the humidity was recorded.

Fifteen dogs were submitted to refrigeration under anesthesia. Two died in the early experiments due to an overdosage of the pentothal sodium. To study the effect of insulin and metrazol on the lowered body temperature, two other animals were sacrificed. Both injections were made when the body temperatures were below 80° F. The observations made thereof were extracurricular, and consequently, were not considered in this report. The remaining 11 dogs passed through the experiments and apparently returned to a normal condition. Two days after completion of the experiments they were observed to be in a normal state of health.

The observations considered in this report are based on the average of all the findings in these experiments, since variations from the average are negligible. For the sake of consistency, the same assistants recorded all the data. No untoward symptoms were encountered. No complications arose.

After the cooling apparatus was put into operation, readings were taken every fifteen minutes, however, now supplemented by the cabinet temperature.

Chart 1 contains changes of body temperature as compared with the cabinet temperature. From an apparent normal body temperature of 100.8°F. , the temperature dropped continuously with refrigeration. The lowest recorded body temperature was 79.5°F. whereas, at the same time, the cabinet temperature was 44°F. It was interesting to note that the cabinet temperature had to drop to 32°F. to make the "holdover" to carry on the lowering process. At this point the compressor was stopped, and as was expected, the body temperature gradually rose along with the cabinet temperature.

Chart 2.

Chart 2.—Time for body temperature to reach lowest point

Chart 3

Chart 3.—Respiration and body temperature

Chart 2 elaborates the changes of body temperature as compared with the time required to make these changes. The $\frac{1}{4}$ H.P. compressor unit required six hours to lower the body temperature from normal to 79.5°F. This time element is striking as compared to the more than eleven hours necessitated for the body temperature to return to normal.

Chart 3 illustrates that respiration which decreased with the lowering of the body temperature was a more sensitive physiologic sign for judging the dog's condition than the pulse. Unlike Charts 1 and 2, Chart 3 is marked by the absence of a "straight" curve by being spotted with a number of fluctuations. The significance lies in the fact that respirations decreased to three per minute with the body temperature at 79.5°F.

Chart 4 compares the pulse changes with those of the body temperature. The former usually dropped along with the latter. When the body temperature registered 79.5°F. , the number of recorded pulsations per minute was 60.

However, the changes of the pulse rate did not occur as acutely as did the respiratory rate.

Chart 5, probably not as significant as the other charts, demonstrates the changes in humidity of the cabinet as related to the body temperature. The humidity rose as the body temperature fell.

Chart 4.

Chart 4.—Pulse rate and body temperature.

Chart 5.

Chart 5.—Humidity of cabinet and body temperature.

SUMMARY

The convenient method of lowering body temperature of dogs by the use of an electrical refrigeration unit has been described. The physiologic changes observed are:

1. The body temperature dropped to 79.5° F. when the interior cabinet temperature was 44° F.
 2. The time required for the above was six hours, almost half the time it took the dog to return to a normal temperature.
 3. The respiration dropped to three per minute when the rectal temperature read 79.5° F. The respiratory rate was a more reliable indication of the condition of the dog than was the pulse rate.
 4. The pulse rate dropped to 60 per minute as the body temperature dropped to 79.5° F.
 5. The humidity of the interior of the cabinet was 72 per cent with the body temperature at its lowest, 79.5° F. This reading became lower as the body temperature increased. The humidity may have been significant as a prophylaxis for pneumonia more than for its physiologic importance.
- Detailed deductions have been withheld pending completion of experiments on diseased dogs.

ALLERGIC PNEUMONIA*

RALPH V. ELLIS, M.D., AND C. A. MCKINLAY, M.D.
MINNEAPOLIS, MINN.

THE importance of the lung as a shock organ in allergic disease is now a commonplace. That true bronchial asthma is a manifestation due to the reaction of hypersensitiveness is universally accepted. In this condition the allergic reaction is confined to the bronchial tree.

A consideration of allergic pneumonia necessitates an entirely different concept. That an allergic response, including the *interstitial pulmonary* tissues, possibly is involved in the production of typical lobar pneumonia (pneumococcal) as well as certain types of pulmonary tuberculosis has long been considered.

However, an extensive pneumonitis on the basis of allergic response to agents other than those of infection is a relatively new and somewhat startling concept; namely, that the interstitial tissue of the lung is capable of sensitization and of reaction to foreign substances. That this may possibly be the case, however, is suggested by numerous reports. Loeffler¹ in 1932 described a disease to which he gave the name, "Flüchtige Sucedan-Infiltrate (mit Eosinophilie)." By 1936 Loeffler² had collected a total of 51 cases, characterized by infiltrative processes in the lung (demonstrated by x-ray), of leucocytosis and eosinophilia. In many instances other symptoms were few or lacking entirely, such cases being discovered through the procedure of group examination for tuberculosis. Reports of a similar condition include those of Busche,³ Wild,⁴ Engle,⁵ and Leitner.⁶ Gravesen⁷ in 1938 reported a case strikingly similar to the one presented in the following report, and suggested an allergic etiology. His patient, like the following, was receiving prontosil medication.

CASE REPORT

History.—S. L., a white male, aged 22 years, a law student at the University of Minnesota, admitted to the hospital January 15, 1939, complained of (1) frequent loose stools, (2) abdominal tenderness, (3) headache, (4) chills and sweats. The history of previous illness was unimportant except in relationship to the present complaints. In October, 1936, while he was in another city, he had a sudden onset of diarrhea, his stools containing bright red blood and mucus, for which he was hospitalized about six weeks. He returned to school in January, 1937. He had occasional recurrences of loose stools, but none were severe prior to the episode responsible for this admission.

Examination.—His temperature on admission was 100.6° F., pulse rate 106, respiration 22. Nutrition was fair. There was moderate abdominal distention with left lower quadrant tenderness. Physical examination otherwise showed nothing remarkable. Proctoscopic examination

Received for publication, May 13, 1940.

Chart 1.

by Dr. H. W. Christianson showed the bowel mucosa studded with pin-point ulcers which bled easily. Treatment prescribed by the proctologist included prontosil by mouth and a streptococcus vaccine parenterally. Prontosil was administered in 15 gr. doses every six hours (60 gr. daily) from January 25 to March 6, inclusive.

Clinical Course.—The illness with which this report is primarily concerned is considered to have started with a recrudescence of fever without other obvious new developments, and at a time when the colitis was showing marked improvement. The temperature was moderately elevated on admission but became normal two days later. During the succeeding week slight elevations of temperature occurred not exceeding 99.4° F. On January 25, the tenth day following admission, prontosil medication was initiated, with two 15 gr. doses at 6 p.m. and 10 p.m., respectively. On succeeding days the patient received four 15 gr. doses at six-hour intervals. On the evening of the eleventh hospital day (first full day of prontosil medication) the temperature rose to 100.8° F., the following day to 102° F., and on the next day to 103.8° F. Chilly sensations were mentioned, and nonproductive cough developed. No abnormal signs were noted on repeated physical examinations. X-ray of the chest on January 31 (seventeenth hospital day) showed marked thickening of the pleura, especially over the left apex, and diffuse increase in the bronchovascular markings, especially in the left lower lobe (Fig. 1).

Fig. 1.

Fig. 2.

Fig. 1.—Seventh day of prontosil administration (Jan. 31, 1939).

Fig. 2.—Fourteenth day of prontosil administration (Feb. 7, 1939)

Physical signs continued to be absent until February 7, when a few fine crepitant râles were noted in the left axilla without other physical signs. X-ray at this time showed multiple areas of abnormal density throughout the left lower lobe and suggested a patchy bronchopneumonia (Fig. 2). Two weeks later x-ray films showed the left lung almost entirely involved and the appearance of an area of increased density on the right (Fig. 3). Crepitant and medium râles were heard over the areas involved without appreciable alteration of resonance, or breath sounds. A pleuropericardial friction rub appeared, accompanied by severe precordial pain; later there was pleural friction. These signs lasted only a few days and there was no effusion. Temperature of an irregular type at moderate to high levels prevailed throughout forty days (Chart 1). Rigors occurred during the height of the process with subsequent peaks of temperature, reaching 105° F., followed by profuse sweating. Cyanosis was not noted and the degree of prostration was so slight as to be indeed remarkable. Dyspnea, paroxysmal in type, was a complaint during a few days at the height of the disease, without obvious change in the physical signs and without cyanosis, but it was relieved in the oxygen tent. Prontosil was discontinued on March 7 after forty days of ad-

ministration, and improvement rapidly ensued. A vaccine which had been given had been discontinued three weeks earlier. The physical signs in the chest cleared and x-ray films on March 25 (fifty-nine days after the onset of the pulmonary symptoms) revealed only a moderate increase in the bronchovascular markings.

On the fifty-eighth hospital day the patient complained of pain in the left groin unaccompanied by obvious physical signs. Femoral phlebitis of low grade was suspected, and this diagnosis became obvious with the development of moderate swelling of the left leg only after the patient was allowed to get up about three weeks later. Aside from this condition, the patient was apparently well at time of discharge, April 4, seventy-three days after admission.

Fig. 3.

Fig. 4.

Fig. 3.—Twenty-first day of prontosil administration (Feb. 14, 1939).

Fig. 4.—Forty-second day of prontosil administration and date of discontinuance (March 7, 1939).

There was no further contact with the patient until the following January, when he re-entered school at the University of Minnesota. At this time the following additional history was obtained: During July the patient took neoprontosil for a few days without apparent reason other than "general principles" (to use his own words) and very shortly developed fever and symptoms of bronchitis (?). A physician was called; he noted râles without other findings. With discontinuance of prontosil the symptoms subsided promptly. No x-ray examination was done at that time.

The general physical examination on January 15, 1940, exactly one year following the hospital admission, was essentially negative. The Mantoux test was negative to 1 mg. of old tuberculin. The x-ray of the chest was also negative (Fig. 6).

Laboratory.—The urine was negative on admission and throughout. The blood on admission showed 8,800 leucocytes and hemoglobin content 95 per cent. The differential count showed polymorphonuclear leucocytes 64 per cent, lymphocytes 26 per cent, eosinophiles 5 per cent, monocytes 4 per cent, and basophiles 1 per cent. Two weeks later the leucocytes had increased to 15,800 and continued around that level to March 6. (See Chart 1 for results of a series of blood counts.) Differential counts were not done after admission until February 26, when an eosinophile count of 33 per cent was discovered. The eosinophiles increased to 46 per cent on March 7 (the date prontosil was discontinued), and then rapidly diminished to 7 per cent ten days later. Blood cultures were repeatedly negative. Agglutination tests on admission, and at two weeks and four weeks later, were negative for *Eberthella typhi*, *Salmonella paratyphi*; and related organisms, *Shigella dysenteriae*, *Brucella melitensis*, and *Pasteurella tularensis*. Sulfanilamide determinations showed a low concentration, consistently only a trace. The leucocyte count January 15, 1940, one year following admission, was 6,100, with 1 per cent eosinophiles. Stool examinations were repeatedly negative for *Entamoeba histolytica* and other animal parasites or ova.

Sputum was never present. Throat culture revealed a few *B. hemolytic streptococci* on one occasion.

The Mantoux test was negative on admission and shortly before discharge.

Culture and guinea pig inoculations with stomach washings were negative for *Mycobacterium tuberculosis*.

DISCUSSION

The occurrence of an unusual type of pneumonia in which massive x-ray findings stood in decided contrast with the slight degree of prostration of the patient, as well as the absence of expected physical findings, had challenged our attention even before high-grade eosinophilia was demonstrated. Eosinophilia has long been recognized as a concomitant of the allergic response. We do not fail to recognize the fact that high-grade eosinophilia is also present in other conditions, occasionally in infections. We feel that such conditions as commonly are associated with eosinophilia were satisfactorily ruled out. Moreover, we do not believe that the pneumonia observed in our patient resulted from microbial invasion. Numerous clinicians of extensive experience were puzzled by it, and bacteriologic methods failed to demonstrate an etiologic agent. Granted that usual bacteriologic methods would have failed in the discovery of a virus as the etiologic agent, clinically it was not virus pneumonia, it did not occur in the course of an epidemic, nor was there any evidence of communicability.

The fever in this case is consistent with a diagnosis of allergic pneumonia, for fever is probably the most frequent symptom of drug allergy, and furthermore, has been frequently recorded in connection with allergy to sulfanilamide. The importance of the recognition of drug allergy as a cause for fever during the treatment of a disease which is in itself accompanied by fever is obvious. The sulfanilamide exhibited in this case was a treatment for ulcerative colitis

and not under the direction of the essayists. Consent to its discontinuance resulted in coincident prompt and complete recovery. The recurrence of similar symptomatology several months later, coincident with a further trial of prontosil, was not, unfortunately, under our own observation. Nevertheless, the history strongly suggests a repetition of the same pulmonary changes we observed. The shorter duration is in keeping with a shorter period of administration of the drug.

SUMMARY

A case of massive, migrating, atypical pneumonia of unusual duration, accompanied by high fever grossly disproportional to the degree of prostration, and a marked eosinophilia, is presented. The condition developed within a few days after initial prontosil administration, continued concomitantly with the use of this drug for six weeks, and cleared up rapidly coincident with its discontinuance. A recurrence of similar pulmonary symptoms not observed by the essayists is reported by the patient following a subsequent trial of prontosil.

We are indebted to Dr. Wesley J. Spink for having called attention to many of the foreign references cited, and who also first suggested the possibility of allergic etiology.

EFFECT OF HISTAMINASE ON THE SHWARTZMAN PHENOMENON*

MILTON D. BOSSE, M.D., PITTSBURGH, PA.

IT HAS been postulated that histamine plays an important role in the production of the Shwartzman phenomenon.^{1, 2} This suggests that histaminase, the specific enzyme which inactivates histamine, might be effective in preventing or modifying the reaction.

The following experiments were carried out in an attempt to determine the effect of histaminase on the Shwartzman phenomenon.

An active extract of *B. proteus* organisms for producing the Shwartzman phenomenon was prepared by a method very similar to that described by Antopol,³ which was based on procedures of Furth and Landsteiner⁴ and Levine and Frisch.⁵

In a preliminary experiment 8 rabbits were each given a preparatory dose of 2.5 mg. of the *B. proteus* extract and a provocative or reacting dose of 0.5

*From the Western Pennsylvania Hospital Institute of Pathology, Pittsburgh, Ralph R. Mellon, M.D., Director.

Received for publication, May 8, 1940.

mg. Four of these animals were pretreated with histaminase.* This histaminase was standardized by the Winthrop Chemical Co., 1 unit being the amount which will inactivate 1 mg. of histamine hydrochloride. The dosages administered orally and subcutaneously varied from 6 to 12 units per kilogram and correspond to six to twelve times the daily oral dose advocated for clinical use by the Winthrop Chemical Co. The intravenous dosages varied from 4 to 30 units per kilogram and correspond to one-third to two and one-half times the doses used by Karady and Browne⁶ on guinea pigs in histamine and anaphylactic shock. The results, as indicated in Table I, Series 1, showed no effect of the histaminase on the skin reaction.

As a result of numerous titrations, it was found that 0.1 mg. of the extract was effective as a preparatory dose, yet produced no gross lesion itself; and that 0.05 mg. as a provocative dose was minimal for eliciting the skin reaction in a high percentage of the animals tested.

Three more series, totaling 34 animals, were given these minimal doses of bacterial extract, and half of each series was pretreated with histaminase. It is seen from the results in Table I that again the histaminase had no striking effect.

TABLE I

RESULTS OF SHWARTZMAN REACTION WITH AND WITHOUT PRETREATMENT WITH HISTAMINASE

	SERIES 1		SERIES 2		SERIES 3		SERIES 4	
	NUMBER HISTA- MINASE RABBITS*	NUMBER CONTROL RABBITS	NUMBER HISTA- MINASE RABBITS†	NUMBER CONTROL RABBITS	NUMBER HISTA- MINASE RABBITS‡	NUMBER CONTROL RABBITS	NUMBER HISTA- MINASE RABBITS§	NUMBER CONTROL RABBITS
Died#	1	1			1			
++++	3	3						
+++			6	5	2	5	2	2
++			1	1	1		1	1
+							1	1
0			1	2	1			

* Death occurring shortly after provocative injection of extract

++++ Hemorrhagic skin reactions more than 4 cm. in diameter.

+++ Hemorrhagic reactions 2 to 4 cm. in diameter.

++ Reactions less than 2 cm. in diameter.

+ Very slight reactions or merely hyperemia.

0 No reaction.

*Enteric-coated histaminase capsules were given each rabbit as follows: 3 units orally five hours before the preparatory injection of extract, 3 units orally two hours after this injection; 3 units orally plus 3 units ground up with 5 c.c. of normal saline injected subcutaneously in the back four hours before the provocative injection, and 3 units subcutaneously immediately after this injection of extract. The suspensions of histaminase for injection were freshly prepared a few minutes prior to use.

†Each rabbit received tablets of histaminase as follows: 10 units ground up with 2 c.c. of normal saline injected subcutaneously six hours before the preparatory injection of extract; a similar injection one hour after the preparatory injection, and the same dose repeated one hour before the provocative injection. The suspensions of histaminase were freshly prepared a few minutes prior to use.

‡Each rabbit received 10 units of histaminase (injectable) powder dissolved in 10 c.c. of saline and injected intravenously fifteen to thirty minutes before the provocative injection of extract.

§Each rabbit received the supernatant fluid from 75 units of histaminase tablets ground finely in a mortar with 10 c.c. of normal saline, centrifuged, and injected intravenously fifteen to thirty minutes before the provocative injection of extract.

Since it requires twenty-four hours for 1 unit of histaminase to inactivate 1 mg. of histamine in vitro, it may be anticipated that the Schwartzman reaction develops too rapidly for histaminase to inactivate any histamine that may be released. The report of Karady and Browne⁶ appears to indicate that histamin-

*A small portion of the histaminase used in these experiments was furnished by the Winthrop Chemical Co., Rensselaer, N. Y., and the remainder, prepared by the same concern, was purchased in open market.

ase acts rapidly in vivo. However, using the same technique and a larger group of animals, Knoll⁷ was unable to confirm their work on anaphylactic shock.

An alternative worthy of consideration is that histamine-like substances rather than histamine itself may be responsible in the Schwartzman reaction. In this case, of course, it would not be expected that histaminase would have any effect on the reaction.

It is also possible that the increase in histamine content of the skin in the Schwartzman phenomenon is secondary, and an effect rather than a cause.

SUMMARY AND CONCLUSIONS

Little or no effect on the Schwartzman phenomenon was noted by pretreatment with histaminase administered orally, subcutaneously, or intravenously in large doses. Either histamine plays little part in the phenomenon or histaminase does not inactivate sufficiently the histamine released.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA WITH HEMOLYTIC ANEMIA (MARCHIAFAVA-MICHELI SYNDROME)*

ARTHUR BUELL, A.B., M.D., AND STACY R. METTIER, A.B., M.D.
SAN FRANCISCO, CALIF.

THE syndrome of paroxysmal nocturnal hemoglobinuria was recorded first by Marchiafava and Nazari in 1911.^{1, 2} In 1931 Micheli³ reviewed all the cases published and added one to the literature. Since then other cases have been recorded by Hamburger and Bernstein,⁴ Witts,⁵ Scott, Robb-Smith, and Seowen,⁶ Dacie, Israels, and Wilkinson,⁷ and Ham.⁸ These authors have described the clinical, pathologic, and laboratory features which have established nocturnal hemoglobinuria as a specific disease.

From a clinical consideration of this disease, certain essential features are recognized. In the cases reported, it occurred most frequently during the second and third decades of life and, following a protracted course, terminated in death.

*From the Division of Medicine, University of California Medical School, San Francisco. Supported by a grant from the Christine Breon Fund for Medical Research. The blood counts were done by Miss Alice McBride. Received for publication, May 20, 1940.

Hemoglobinuria was the predominant sign and occurred almost always at night, frequently accompanied by vague abdominal pains. The course of the illness was characterized by recurring attacks of fever which were usually intermittent, a predisposition to venous thrombosis and phlebitis, and a slight icteric tint to the sclerae and skin. By the use of suitable reagents, hemosiderin and hemoglobin could be demonstrated in the urine. In a few cases slight enlargement of the spleen was reported.

The blood changes in nocturnal hemoglobinuria are most striking. In the cases reported in the literature, between one and three million red blood cells per cubic millimeter were noted. In most instances the cells were slightly larger than normal, so that the anemia was usually macrocytic, in others, it was normocytic. The hemoglobin was reduced to between 18 and 50 per cent of normal; hyperchromia was noted in some cases and hypochromia in others. Whenever hemolysis had occurred recently, hypochromia and consequently a lower color index were observed. In general, therefore, there was a tendency to slight macrocytosis (M.C.V. 100 cubic microns) and hypochromia of the red blood cells (M.C.H.C. 27 per cent). In all instances the anemia was refractory to treatment. The resistance to hypotonic salt solution was within normal range, and an examination of so-called "wet preparations" failed to show the presence of spherocytes. The outstanding feature was a persistent reticulocytosis. Invariably there was a leucopenia with a relative lymphocytosis and a moderate thrombocytopenia. Examination of the sternal bone marrow by either puncture or biopsy showed hyperplasia of the erythropoietic elements.

The etiology of hemoglobinuria is somewhat obscure. From a study of the reports in the literature it was apparent that, in contrast to familial hemolytic icterus, a familial predisposition did not exist in patients with nocturnal hemoglobinuria. Dacie, Israels, and Wilkinson,⁷ and Ham,⁸ were able to show by experiments both in vivo and in vitro that increased carbon dioxide tension was of critical importance for the production of hemolysis.

The following case of nocturnal hemoglobinuria is presented first, because of the rarity of the condition and, secondly, to record the results of in vitro studies showing increased hemolysis of red blood cells in media at an acid pH. The patient had an illness of several years' duration characterized by anemia, vague abdominal pain, thrombophlebitis, and hemoglobinuria occurring at night.

REPORT OF A CASE

History.—A. J., an American woman, single, aged 43 years, was first admitted to the University of California Hospital on May 31, 1938. She complained of weakness and stated that she was known to have been pale and anemic for at least six years. Five years previous to her present entry she had suffered profuse uterine bleeding which was relieved by salpingophorectomy and hysterectomy. Despite the cessation of menses, however, she continued to be anemic, and on two occasions obtained temporary relief from transfusions. In 1935 she had an attack of phlebitis in the right leg which persisted for several months. She had a similar attack in August, 1937, and in November, 1937, the veins of the left leg became involved. At this time she first noticed that her skin had a slightly yellowish tinge and experienced vague abdominal pains which were most marked at night. She then noticed that the urine passed on arising in the morning was very dark. In December, 1937, her physician told her she had had a hemorrhage from her kidneys. This episode lasted about one week and recurred about a month later.

Physical Examination.—On entry to the hospital the patient was well developed, moderately well nourished, looked tired and pallid, and had slightly icteric sclerae. The ears,

nose, throat, and lymph nodes presented no remarkable abnormalities. The teeth were carious, but the gums were firm and showed no bleeding points. There were no signs of disease in the heart or pulmonary parenchyma. The blood pressure was 122 systolic and 68 diastolic. Neither the spleen nor the liver could be felt on palpation. There was slight pitting edema of the ankles.

Laboratory Data. Examination of the blood showed red blood cells 1,970,000 per cubic millimeter, hemoglobin 56 per cent (7.8 Gm. Sahli), and leucocytes 2,200 per cubic millimeter. The differential count showed polymorphonuclear leucocytes 61 per cent (29 per cent filamented, 32 per cent nonfilamented forms), eosinophiles 3 per cent, basophiles 2 per cent, and small lymphocytes 34 per cent. The reticulocytes were 3 per cent. The volume of packed cells was 25 c.c. per 100 c.c. of blood. The mean corpuscular volume was 126 cubic microns, the mean corpuscular hemoglobin was 39 micromicrograms, and the mean corpuscular hemoglobin concentration was 31 per cent. The color index was 1.39, the volume index 1.47, and the saturation index 0.93. The fragility of the red blood cells established with the usual hypotonic saline solutions was within normal range. The rate of sedimentation of the erythrocytes was 24 mm. in one hour (corrected Wintrobe method). The reactions to the Wassermann and Kahn tests of the blood were negative. The phenolsulphonphthalein excretion tests showed normal renal function. No abnormalities of the kidneys were observed in the retrograde pyelograms. The determination of liver function by using the rose bengal dye showed normal excretion. The total blood serum protein was 5.82 Gm. per 100 c.c., of which 3.54 Gm. was albumin and 2.28 Gm. was globulin; the ratio of albumin to globulin was 1.55. Absence of hydrochloric acid from the gastric secretion was demonstrated by parenteral injection of histamine. Roentgenograms of the gastrointestinal tract and of the long bones revealed no abnormalities.

Bone marrow removed from the sternum for biopsy was examined by the usual technique of Zenker's fixation and staining with hematoxylin and eosin. It showed a general hyperplasia of both erythropoiesis and myelopoiesis. Large numbers of cells containing pyknotic nuclei and hemoglobin, and an abundance of younger forms with basophilic cytoplasm and large, deeply stained nuclei were observed. These were considered to be normoblasts and erythroblasts. No megaloblasts were seen. Only a few myeloblasts were noted, but there were large numbers of cells ranging from the stage of myelocytes to the fully developed polymorphonuclear leucocytes. The diagnosis was moderate generalized hyperplasia of erythropoiesis and leucopoiesis.

Course of Illness.—Repeated examination of the blood showed only little change in the red blood cells and their hemoglobin content, but the reticulocytes varied in number from 3 to 10 per cent of the total count. Ten days after entry the patient was discharged from the hospital to her physician who was advised to give her liver extract potent in pernicious anemia by injection and large doses of iron by mouth. In spite of this treatment the anemia persisted.

Second Entry. On August 19, 1938, the patient was readmitted to the hospital complaining that she had secreted dark urine for ten days. She stated that, except for weakness, she had felt about as usual until the present episode, when she began having chilly sensations, vague abdominal pains, and a daily afternoon rise in temperature to 100° F. She passed large quantities of bright red urine, which upon analysis by her physician was reported to contain blood.

TABLE I

	1:30 A.M.	7 A.M.	9 A.M.	NOON	3 P.M.	9 A.M.
Hemoglobin	++	++	0	0	0	0
Bile	0	0	0	0	0	0
Urobilin	1:10	1:50	1:10	0	0	0

The physical examination was essentially the same as previously reported.

Laboratory Data. The urine showed no bile, albumin, sugar, or casts. Urobilinogen was noted in a concentration of 1:50 dilution units in specimens obtained at 7 A.M., and 1:10 in specimens obtained at noon. Hemoglobin was present in specimens of urine obtained at

1:30 A.M. and 7 A.M., but was absent in specimens obtained after 9 A.M. (see Table I). Because of the presence of the hemoglobin in the urine, the patient's illness was recognized as paroxysmal nocturnal hemoglobinuria of the Marchiafava-Micheli type.

Special Procedures. A set of serologic experiments was arranged similar to those performed by Dacie, Israels, and Wilkinson.⁷ Serum oxalated plasma and heparinized plasma were used as hemolytic media. Duplicate series were set up with serum and plasma of a normal person of the same blood grouping (Moss II).

1. The patient's red blood cells, after having been carefully washed with physiologic salt solution, were added to tubes containing the patient's serum and plasma, and to tubes containing serum and plasma obtained from a normal person. The normal person's red blood cells were added to a series of tubes containing similar media. All tubes were placed in a water bath at a temperature of 37° C. One-tenth cubic centimeter of packed red blood cells was added to 1.0 c.c. of plasma or serum in each instance. The results are summarized in Table II. It is to be noted that a slight amount of hemolysis occurred when the patient's cells were mixed with her own and with normal serum. There was no hemolysis of the normal cells in similar preparations.

TABLE II

SHOWING A MARKED DEGREE OF HEMOLYSIS OF THE PATIENT'S RED BLOOD CELLS WHEN THE MEDIA ARE SLIGHTLY ACIDIFIED

	PHYSIO- LOGIC SALT SOLUTION	PA- TIENT'S SERUM	PA- TIENT'S OXALATED PLASMA	PA- TIENT'S HEPARIN- IZED PLASMA	NORMAL SERUM	NORMAL OXALATED PLASMA	NORMAL HEPARIN- IZED PLASMA
Patient's cells	0	Slight	0	0	Slight	0	0
Normal cells	0	0	0	0	0	0	0
Patient's cells {CO ₂ in solution	0	+++	+	++	++	+	++
Normal cells {CO ₂ in solution	0	0	0	0	0	0	0
Patient's cells {chilled serum		0	0		0	0	
Normal cells {chilled serum		0	0		0	0	
Patient's cells {chilled serum CO ₂ in solution		+++			+++	+	
Normal cells {chilled serum CO ₂ in solution		0	0		0	0	

2. Duplicates of the above procedures were set up, and carbon dioxide in 5 per cent dilution was bubbled through the serum and plasma. The results are also summarized in Table II. It is to be noted that in the acidified media definite hemolysis occurred in all solutions containing the patient's cells. In the tubes containing plasma (of the normal person and the patient), which had been treated with sodium oxalate to prevent coagulation, hemolysis was less marked. The hemolysis which occurred in the tubes containing normal cells with the serum of the normal person and the patient was negligible.

3. To determine whether or not there was a positive Donath-Landsteiner reaction, the serum and oxalated plasma were chilled prior to the addition of the red blood cells and the carbon dioxide gas. It is apparent from the data recorded in Table II that hemolysis was not increased by the low temperature.

4. In another series of experiments serum was heated to 56° C. The cells of the patient and those of the normal person were added to this serum. No hemolysis occurred even after bubbling the carbon dioxide gas through the serum. The hemolytic activity of the serum was not restored by the addition of complement. These results are summarized in Table III. This demonstrated that evidently the lysin was thermolabile and that the previous reactions were not due to a complement-fixation mechanism.

TABLE III

Treatment.—Since in vitro experiments showed an increased hemolysis at an acid pH, it was thought that the administration of large amounts of alkali might favorably alter the lytic mechanism. Accordingly, the patient was given a sufficient amount of sodium bicarbonate (4.0 Gm. four to six times a day) to render the urine alkaline (pH 7.6). However, during this treatment the patient had more severe abdominal pain and hemoglobinuria than before.

The oral administration of large doses of iron, the parenteral administration of liver extract effective in the treatment of pernicious anemia, together with a high protein diet, autolyzed yeast, and a period of multiple transfusions failed to increase the production of hemoglobin or red blood cells.

DISCUSSION

The diagnosis of our patient presented a considerable problem. She had an anemia probably of hemolytic origin accompanied by slight icterus and reticulocytosis. The degree of the anemia, the macrocytosis, the leucopenia, and the slight thrombocytopenia were suggestive of pernicious anemia. However, the failure of the bone marrow to respond to liver therapy removed this possibility from further consideration. The resistance of the red blood cells to hypotonic salt solution within normal range, the negative family history, and the absence of an enlarged spleen excluded the possibility of hemolytic icterus of familial origin. Studies of the urine during the patient's first hospitalization were inadequate, but during the second hospitalization discovery of the nocturnal emission of hemoglobin led to the recognition of the anemia as the hemolytic type described by Marchiafava.¹

No adequate explanation can be offered for the abnormal hemolytic mechanism in this patient. Special procedures were carried out according to the methods described by Dacie, Israels, and Wilkinson,⁷ and Ham.⁸ Our results

were comparable to theirs. After adding the patient's washed red blood cells to her serum and to normal serum, a slight degree of hemolysis was observed. When the media were acidified with carbon dioxide, the hemolysis was greatly increased. When the serum was heated to 56° C., the hemolytic activity was destroyed. It seems apparent from these studies that the patient's red blood cells were sensitized to some lysin present in her own serum and in normal serum. The role that hydrogen-ion concentration of serum or plasma may play in the production of the lysin deserves further investigation.

SUMMARY

The clinical and laboratory findings in a patient with nocturnal hemoglobinuria are presented. The possible significance of increased hydrogen-ion concentration in the production of lysin is briefly discussed.

Since this paper was written, the patient died (Feb. 19, 1940). The cause of death was reported to be due to cerebral thrombosis. The spleen was normal in size.

FALSE POSITIVE SEROLOGIC REACTIONS FOR SYPHILIS IN INFECTIOUS MONONUCLEOSIS*

ROBERT E. KAUFMAN, M.D., NEW YORK, N. Y.

MANY diseases besides syphilis may be accompanied by positive serologic reactions ordinarily considered diagnostic of syphilis. In malaria, during the acute stage, there is very frequently a transiently positive Wassermann or flocculation reaction.¹ Trypanosomiasis, relapsing fever, and ratbite fever are sometimes attended by temporarily positive tests.² Some patients with lymphogranuloma venereum³ and with kala-azar^{4, 5} also show such reactions. Approximately 60 per cent of leprosy patients have positive serology; and in yaws positive complement fixation and flocculation reactions occur as regularly as in syphilis.⁶ Christie⁷ has recently emphasized that many infants born to Wassermann-positive syphilitic mothers have positive serology at birth. In most instances this disappears without treatment and, therefore,

*From the Lenox Hill Hospital, New York City.
Received for publication, May 21, 1940.

represents merely the passage of reagin through the placenta. Serologic tests, in various degrees of positivity, have also been reported following vaccination for variola,^{8,9} and in cases of malignant neoplasms, jaundice, hyperpyrexia, pulmonary tuberculosis, typhoid, typhus, scarlet fever, "herpes genitalia," gonorrhea, "angina," bronchitis, and most often in upper respiratory infections and lobar pneumonia.¹⁰⁻¹³ However, the following statement is made by no less an authority than Eagle⁶: "The statistical reports of the past 10 to 15 years make it reasonably certain that neither tuberculosis, diabetes, pregnancy, anesthesia, malignancy, jaundice, fever, nor hypercholesterolemia predisposes to false-positive reactions."

A small number of references to the occurrence of false positive serologic reactions in infectious mononucleosis have appeared in the literature of the past decade. Weber¹⁴ in 1930, and Weber and Bode¹⁵ in 1931, reported 3 such cases with positive Wassermann and Meinicke tests. Gooding¹⁶ in 1931 stated that 16 of 27 patients with infectious mononucleosis gave either a positive or a doubtful Wassermann reaction, and that those patients who showed a negative Wassermann test in most instances showed a positive Kahn test. He stated further that the Wassermann reaction returned to negative spontaneously six to eight weeks after the acute stage. Unfortunately, details concerning the positive tests and the return to negative are most meager, so that it is not possible to say exactly how many of these cases should actually be included. One positive serologic test followed by repeated negative tests should not entitle a case to be included in our discussion, since this may represent merely a technical or clerical error.

Hatz¹⁷ in 1938 published one clear-cut case with strongly positive transient Wassermann reactions and simultaneously negative Kline tests. The next year Saphir¹⁸ reported one case with strongly positive Wassermann and Kahn reactions on several occasions, which became negative within several weeks without antisyphilitic treatment. Also in 1939 Sadusk¹⁹ described a patient whose blood gave temporarily positive reactions with the Kahn and the cholesterolized Wassermann antigens, and negative reactions with the alcoholic antigen. This case was definite; but the author incidentally mentions 2 others which are doubtful, since in both instances "weakly positive" reactions, reported on only one occasion, were not confirmed.

Bernstein² published an excellent account in 1938 of 6 cases in which the Wassermann or the Eagle flocculation test, or both, became temporarily positive during the course of infectious mononucleosis. Two of these cases had previously been reported by him.²⁰ Of the 6 cases, one had a "doubtful" Eagle, a negative Wassermann, and no further tests. This case should, in my opinion, be excluded from such a series. In a recent monograph on infectious mononucleosis, Bernstein²¹ states that 8 cases with false positive serology have been observed by him at the Johns Hopkins Hospital, thus adding 2 new cases to those previously reported.² The cases described by Löbe and Rosenfeld,²² Radford and Rolleston,²³ Wawersig,²⁴ and Asahina²⁵ should all be left out of any tabulation of false positive serologic reactions in infectious mononucleosis for one of two reasons: either the diagnosis of infectious mononucleosis was not certain or syphilis was not definitely excluded.

The incidence of false positive serologic reactions in infectious mononucleosis is difficult to determine with any degree of accuracy. According to the combined series of Gooding,¹⁶ Saphir,¹⁸ Sadusk,¹⁹ Bernstein,²¹ and myself, there were 29 patients with false positive reactions out of 183 patients with infectious mononucleosis who had serologic tests for syphilis performed. This gives an incidence of 15.8 per cent. But if Gooding's series—which is so contrary to the experience of all other clinicians—were excluded, the incidence would be only 8.4 per cent.

In contrast to these figures are the unpublished observations of several careful investigators²⁶ who, although they have heard indirectly of 2 or 3 unpublished cases of false positive reactions in infectious mononucleosis, have not personally observed a single such case in a combined experience of between 150 and 250 serologically tested patients. The actual incidence of recognized false positive reactions would, therefore, seem to be between 2 and 10 per cent. But as Bernstein² has stated: "It should be emphasized that the evanescent character of these positive serological reactions mitigates against the likelihood of recognizing all the instances in which they occur. It is reasonable to assume, therefore, that if these serological tests were carried out more regularly and persistently, the incidence of positive reactions encountered would be considerably higher."

Among 82 proved cases of infectious mononucleosis that I have investigated during the past three years, there were 3 with false positive serology. Sixty-four of the 82 had at least one serologic test for syphilis performed during the acute stage of the illness, and 32 of these had such tests on 2 or more occasions. The diagnosis of infectious mononucleosis was established by the clinical course, typical blood smears, and sheep cell agglutination tests. Two of the patients were known to have congenital syphilis with negative serology following antisypilitic treatment. It is interesting to note that in neither case did the Wassermann reaction revert to positive during the course of infectious mononucleosis.

CASE REPORTS

CASE 1.—The first patient with false positive serology was a male pharmacy student, aged 22 years, who had had high fever, several chills, severe frontal headache, profuse sweats, marked fatigue, and general malaise for ten days prior to admission. He was sent to the hospital with the tentative diagnosis of typhoid fever. On admission he was found to have a markedly congested pharynx, slight enlargement of the spleen, marked hyperesthesia of the skin over the abdomen, and tenderness in the left lower quadrant. There was considerable

enlargement of the axillary, inguinal, and epitrochlear lymph nodes, all of which were firm and very tender. There were also a few small nontender left posterior cervical and bilateral anterior cervical nodes. The blood smear showed 12 per cent polymorphonuclear leucocytes and 88 per cent lymphocytes. The total white blood cell count was 13,400; and the red blood cell count and hemoglobin were within normal limits. On the fourteenth day of illness the monocytes numbered 11 per cent, and in the fifth week 40 per cent. Agglutination tests for typhoid and paratyphoid A and B infections were negative on two occasions. The results of the other serologic tests are shown in Table I.

CASE 2.—A male interne, aged 25 years, was admitted after having had a sore throat, cough, chills, and fever for one day. Examination revealed only a congested nasal mucosa and pharynx. The initial diagnosis was gripe. By the sixth day of illness he had a severe cough, high fever, mild conjunctivitis, and slight enlargement of the posterior cervical lymph nodes bilaterally. A positive sheep cell agglutination test and characteristic blood smears soon established the diagnosis of infectious mononucleosis. On the fourth day of illness the white blood cells were 11,400; polymorphonuclear leucocytes were 78 per cent, of which 27 were immature; lymphocytes 10 per cent; monocytes 12 per cent. On the ninth day the white blood cells numbered 15,000; polymorphonuclear leucocytes were 73 per cent, of which 40 were immature; lymphocytes 7 per cent; monocytes 4 per cent; eosinophiles 3 per cent; abnormal cells of the mononuclear series 13 per cent. Eight weeks after the onset a smear showed the following: polymorphonuclear leucocytes 39 per cent; lymphocytes 8 per cent; monocytes 9 per cent; eosinophiles 2 per cent; abnormal cells of the mononuclear series 42 per cent. The second blood smear was suggestive of infectious mononucleosis; subsequent ones were typical. The results of the various serologic tests performed in four different laboratories (a, b, c, d) are shown in Table II.

CASE 3.—A male child, aged 2½ years, was seen in the pediatric clinic after having had fever and anorexia for one week. A pin-point vesicular eruption was present over the entire body; the tonsils were enlarged and congested; there was a generalized lymphadenopathy; and the temperature was 104.2° F. Varicella was diagnosed and the child was

sent home. Two weeks later he was admitted to the hospital, since the fever, marked fatigue, and anorexia had continued, and there were in addition occasional vomiting and enuresis. Examination revealed temperature 100.6° F., pulse rate 104, respirations 24. There was a left catarrhal otitis media, injected tonsils and pharynx, and generalized lymphadenopathy.

A Widal test, a tuberculin test, and several urine examinations were all negative. A blood count, done the day before admission, showed white blood cells 17,000, polymorphonuclear leucocytes 4 per cent and lymphocytes 96 per cent. The following day the figures were hemoglobin 88 per cent, red blood cells 4,400,000, white blood cells 4,200, polymorphonuclear leucocytes 50 per cent, and lymphocytes 50 per cent. Four days later the smear showed polymorphonuclear cells 10 per cent, lymphocytes 29 per cent, monocytes 16 per cent, eosinophiles 1 per cent, and abnormal cells of the mononuclear series 44 per cent. The serologic reactions reported by several laboratories are summarized in Table III, wherein the headings "Kline" and "Eagle" refer to the Kline diagnostic and the Eagle micro-flocculation tests.

DISCUSSION

What is the significance of a positive Wassermann or flocculation reaction during the course of infectious mononucleosis? In the first place, the patient may have syphilis, in which case the tests will remain positive. Secondly, the positive report may represent a technical error, in which case all subsequent tests will be negative.²⁷ Thirdly, the result may be and usually is a biological false positive reaction. It may happen that a positive Wassermann report is obtained before the diagnosis of infectious mononucleosis has been definitely made or even considered. One should, therefore, observe the dictum of Bernstein: "Whenever, in the course of any disease a Wassermann, suspected of being falsely positive, is encountered, a Paul-Bunnell [sheep cell agglutination] test should be performed." Even if the latter is negative, the patient may still have infectious mononucleosis.²⁸

Krag and Lonberg,¹² on the basis of a very large serologic experience, state: "If the positive [Wassermann] reaction at the first retest is constant and a thorough clinical-anamnestic investigation is completely negative, nothing

quantitative relationship between the heterophile antibodies, which give rise to the Paul-Bunnell reaction, and the substances responsible for the positive complement-fixation test (Wassermann) or for the various flocculation tests (Kline, Kahn, Eagle, Meinicke, etc.). As the cases in this paper illustrate, the same serum may give positive reactions with some tests for syphilis and negative reactions with other tests; different laboratories using presumably the same test may get totally different results with the same serum; and a positive test may be negative on the next examination, whereas a test previously negative may become positive. False positive reactions do not seem to be more frequently encountered with one serologic test than with another (Table IV), except in so far as certain tests, such as the Wassermann, are more commonly employed.

What is the cause of the false positive serologic reactions for syphilis occasionally noted during the course of infectious mononucleosis? According to Eagle's authoritative book on the laboratory diagnosis of syphilis,¹ there is likely to be some effect of native amboceptor (antibody for sheep red blood cells) on the Wassermann test. "Whereas small amounts of native amboceptor tend to give negative Wassermann reactions because hemolysis is accelerated, large amounts of native amboceptor, such as those usually observed in infectious mononucleosis, tend to cause such massive agglutination of the red blood cells as to retard hemolysis and therefore give a false positive result."² However, the possibility of a false positive flocculation test (Kline, Kahn, Eagle, Meinicke, etc.) being due merely to native amboceptor is clearly excluded, since red blood cells are not employed in this type of test. "The sera giving false-positive reactions apparently contain some reagin-like factor which reacts with beef heart lipid in a manner indistinguishable from syphilitic serum."³

The etiologic agent in infectious mononucleosis is at present unknown. Perhaps the occurrence, even though rarely, of false positive serologic tests for syphilis may offer a clue. Bernstein² has suggested that "the causative agent in infectious mononucleosis may contain a substance having antigenic properties in common with the *Treponema pallidum*; or else this causative agent may liberate from the tissues of the patient a reagin-like material. The fact that the majority of the diseases which may be associated with a positive Wassermann are caused by protozoa [including spirochetes as protozoa] would suggest that the causative agent of infectious mononucleosis may likewise be a protozoön."

SUMMARY

1. A review of the literature of false positive serologic tests for syphilis during the course of infectious mononucleosis has been presented.
2. Three additional cases were observed among 64 patients who had Wassermann tests performed.
3. The suggestion is made that patients should not be treated for syphilis until serologic tests, suspected of being falsely positive, have had a sufficient chance—about twelve weeks—to revert to negative.
4. The significance of a positive Wassermann or similar reaction during the course of infectious mononucleosis has been discussed.

¹ I wish to express my sincere thanks to the following for their kind aid: Doctors Alan Bernstein, Israel Davidsohn, Harry Eagle, Stephen Gumpert, John Koopman, Perry Manheims, Leo Spiegel, and Annis Thomson.

EXPERIMENTAL UTEROTUBAL INSUFFLATION*

FURTHER INVESTIGATIONS

HERBERT F. NEWMAN, M.D., AND MAX D. MAYER, M.D., NEW YORK, N. Y.

IN A PREVIOUS communication¹ there were described some elementary features of uterotubal physiology as determined by insufflation of gas according to the method of Rubin. Uterotubal kinetics are analogous to those of other smooth muscle organs in that they are affected by the autonomic nervous system.

The present experiments were undertaken to evaluate the influence exerted by the extrinsic nerves upon the Fallopian tubes and uteri of rabbits, as determined by means of transuterine insufflation of gas. The influence of induced ovulation was also studied.

The female rabbit has a double uterus ending in a single vagina. Each uterus and its tube lie at the free end of a thin, highly vascularized mesentery. The uterine and ovarian vessels form multiple arcades, and anastomose close to the free border of the mesentery. The extrinsic nerves to the pelvic genitals pass through the mesentery, lying either free or in close conjunction to the vessels. There is probably a dual, anatomical innervation with one group of nerves following the ovarian and the other the uterine vessels.²

METHOD

Young female rabbits, weighing 2.2 to 5.4 pounds, were insufflated by the technique previously described. The effect of nerve block as induced by infiltration of the uterine or tuboovarian mesentery with 2 per cent procaine hydrochloride was studied. Direct electrical stimulation of the mesentery was attempted, but the contractions of the smooth muscle in the mesentery itself rendered the resultant kymographic tracing difficult to interpret. Trausection of the spinal cord was found to be so shocking as to invalidate conclusions at this time. An attempt was made to divide the mesentery, leaving the blood supply intact, but the operation was difficult to perform without introducing mechanical factors and at the same time it was impossible to eliminate the presence of undivided nerve fibers traveling in the vascular sheaths.

EXPERIMENTAL FINDINGS

The features of the curve that are particularly emphasized are: (1) Primary pressure peak—level at which gas enters the abdominal cavity. (2) Plateau level—general level of pressure during insufflation. (3) Small waves of fluctuation in pressure during insufflation.

Nerve Block of the Uterine Mesentery.—In 11 animals 1.0 to 1.5 c.c. of procaine was injected throughout the uterine mesentery from the cervix to the uterine cornu. Four animals were observed without any systemic anesthesia,

*From the Laboratories of the Sydenham Hospital, New York.
Received for publication, May 27, 1940.

and in the other 7 efficient narcosis was elicited by intravenous nembutal. After a preliminary control insufflation and when a fairly constant plateau level of insufflation was observed, the procaine was injected. Changes in the nature of the curve appeared within three to sixty seconds after injection.

TABLE I

PLATEAU PRESSURE LEVEL OF CONTROL	PLATEAU LEVEL AFTER PROCAINE	FALL
mm. Hg	mm. Hg	mm. Hg
112	58	54
90	45	45
75	50	25
72	48	24
70	58	12
57	28	29
55	45	10
50	45	5
48	25	13
45	42	3
45	40	5

1. Effect upon plateau level of insufflation. This level fell in all 11 animals. The range of fall was between 3 and 54 mm. Hg, and the amount of fall was less as the control plateau level approached 45 mm. Hg (Figs. 1 and 2).

2. Effect upon the character of the small waves of pressure.

(a) In 7 animals there was no apparent change in the nature of the waves.

(b) In 2 animals after a fall in the plateau level the waves became deeper and more regular.

(c) In one animal after procaine block of the uterine mesentery the plateau level fell only 3 mm. Hg, but the small waves of pressure which had been observed in the control period disappeared completely. In another animal the plateau level fell from 72 to 48 mm. Hg, and all the waves similarly disappeared. In both of these animals reinsufflation was performed and all the waves reappeared (Fig. 3).

3. Effect upon the tracing gained through reinsufflation. This was performed in 7 animals.

(a) In all cases the primary peak at which gas entered the abdominal cavity was lower in the second insufflation obtained after blocking the uterine mesentery than in the control tracing. The arithmetic mean for the first tracing was 109 mm. Hg and for the second was 62 mm. Hg. This decrease is not to be attributed solely to procaine, for it has been shown that simple reinsufflation of itself lowers the primary pressure peak. (In a group of ten animals who were reinsufflated without procaine injection the mean for the primary peak of the first tracing was 130 mm. Hg and of the second 79 mm. Hg).

(b) In all cases the plateau level of the second insufflation was the same or slightly lower than that obtained under procaine.

(c) The small waves of pressure usually appeared more regularly and were deeper than in the previous insufflation.

4. Saline infiltration of uterine mesentery. In 3 animals saline solution in 1 to 1.5 c.c. amounts was injected into the uterine mesentery to rule out any mechanical effect of fluid distention. In 2 animals no change in the tracing

Fig. 1.—Effect of procaine injection of the uterine mesentery. Primary peak—174 mm. Hg. Plateau level—90 mm. Hg. At A, injection of 1 c.c. of 2 per cent procaine hydrochloride into the uterine mesentery. Note. Immediate drop to level of 13 mm. Hg and maintenance of level upon re-insufflation at B and C.

Fig. 2.—Effect of procaine injection of the uterine mesentery. Primary peak—92 mm. Hg. Plateau level—57 mm. Hg. At A, injection of 1 c.c. of 2 per cent procaine hydrochloride into the uterine mesentery. Note. Drop to level of 28 mm Hg and maintenance of level upon re-insufflation at B.

occurred. In one animal the plateau level fell 7 mm., but the character of the tracing remained the same. In all 3 cases procaine was then injected into the areas previously infiltrated with saline. In 2 of the 3 animals the plateau level was decreased about 15 mm. Hg (there was considerable dilution of the procaine by previously injected saline), and the reinsufflation curves were similar to those seen under procaine insufflation.

5. In one animal no gas entered the cavity, although a pressure of 200 mm. Hg was reached. The animal was reinsufflated and the uterine mesentery injected with procaine while the pressure was still rising. Gas entered to form a primary peak at a level of 175 mm. Hg and fell to a plateau of 70 mm. Hg. Another cubic centimeter of procaine was injected into the mesentery, and the level fell further to 55 mm. Hg. On reinsufflation the primary peak was at a level of 88 mm. Hg and the plateau was 60 mm. Hg.

TABLE II

CONTROL PRIMARY PEAK	PLATEAU	UNDER TUBOOVARIAN BLOCK	UNDER UTERINE BLOCK
mm. Hg	mm. Hg		
108	78	98, fell to 78	64
170	95	135, fell to 60	
124	63	45, reinsufflated to produce a primary of 90 and plateau of 45	30
168	80	Up to 100	45
152	52	Up to 58	To 35 and rose gradually to 53

TABLE III

RATE OF GAS FLOW IN C.C./MIN.	PRIMARY PRESSURE PEAKS IN MM. HG	
	OVULATING	NONOVULATING
11	140	108
15	148, 78	143
18	155, 105, 90	117
19		152, 142
20	158, 127, 54	
21	200, 50	200, 168, 168, 124, 119, 100
22		200, 100
24		168
25		115
27		183
28	128	80, 65
30	74	174
32		92
35	173	150
37		
40	100	174
42		88
50		

Nerve Block of the Tuboovarian Mesentery.—1. In 2 rabbits 1 c.c. of saline was injected into the tuboovarian mesentery and no change was observed in the tracing.

2. In a rabbit whose uterine mesentery had previously been injected with procaine to produce a slight fall in plateau level, injection of the tuboovarian mesentery produced no change.

3. In 5 experiments procaine was first injected into the tuboovarian mesentery. In 4 of these cases the plateau level rose slightly while in one case it fell. In 4 cases the uterine mesentery was then infiltrated with procaine and a fall was observed in the plateau level in all cases (Figs. 4 and 5)

Fig. 3.—Effect of procaine injection of the uterine mesentery. Primary peak—88 mm. Hg. Plateau level—72 mm. Hg. At A, injection of 1 c.c. of 2 per cent procaine hydrochloride into the uterine mesentery. Note: Drop to level of 48 mm. Hg and disappearance of all waves on the tracing. On re-insufflation at B, the waves returned

Fig. 4.—Effect of block of the tuboovarian mesentery followed by block of the uterine mesentery. Primary peak—108 mm. Hg. Plateau level—78 mm. Hg. At A, injection of 1 c.c. of procaine into the tuboovarian mesentery. At C, re-insufflated. At D, another cubic centimeter of procaine injected into the uterine mesentery. At E, another cubic centimeter of procaine injected into the tuboovarian mesentery. Note: Drop in levels on injecting the uterine mesentery and rise in levels upon injecting the tuboovarian mesentery.

Effect of Induced Ovulation.—In 15 animals ovulation was induced by the injection of human pregnancy urine. Ten cubic centimeters of urine were injected two days in succession, and on the third day insufflation was performed. The effect upon the primary pressure peaks was compared to that of 23 non-ovulating animals.

The arithmetic means for the two groups are 104 for the ovulating animals and 136 for the nonovulating. This difference is insignificant in view of the scattering.

DISCUSSION

We have demonstrated that definite changes are observed in the kymographic tracings after blocking the uterine mesentery with a local anesthetic.

The actual part played by the ovarian plexus as compared to the uterine, as well as the factors of the sympathetic as opposed to parasympathetic innervation, have not as yet been elucidated.

Fig. 5.—Effect of block of tuboovarian mesentery followed by block of uterine mesentery. The animal was insufflated at A with no gas passing into abdominal cavity. Reinsufflated at B at the same rate of gas flow. Primary peak—168 mm. Hg. Plateau level—80 mm. Hg. At C, 1 c.c. of procaine injected into the tuboovarian mesentery. At D, 1 c.c. of procaine injected into the uterine mesentery. At E, the rate of gas delivery was increased from 20 to 100 c.c. per minute. Note: Rise in level after injecting the tuboovarian mesentery and fall in level after injecting the uterine mesentery. On speeding the rate of gas delivery five times, the level rose 35 mm. Hg and gradually fell.

In a previous communication it was demonstrated that upon simple re-insufflation of rabbits both the primary peaks and the plateau levels fall to reach a constant level after about thirty minutes of insufflation. This particular level is promptly reached after the injection of procaine into the uterine mesentery. Furthermore, although an increase in gas rate increases the primary peak and the plateau levels,¹ upon continuing the insufflation the level falls to reach that obtained at slower rates of flow. This phenomenon has been observed in animals whose uterine mesentery has been blocked. Thus there seems to be a basic level of insufflation pressure, or plateau level, which is kept fairly constant by some intrinsic compensating mechanism, irrespective of time, nerve impulses, and delivery rate.

The obvious clinical applications of these findings are now being studied on patients, with particular reference to the case management of sterility and the relief of dysmenorrhea.

NONFILAMENT-FILAMENT RATIO CHANGES FOLLOWING ADMINISTRATION OF AUTOGENOUS VACCINES TO PERSONS WITH LOW-GRADE CHRONIC ILLNESS

MERRITT H. STILES, M.D., F.A.C.P., PHILADELPHIA, PA.

IT HAS been stated that the ratio of immature to mature neutrophilic leucocytes parallels the activity of an infectious disease process¹ and the severity of symptoms,² and that clinical improvement in patients with low-grade chronic illness is accompanied by proportionate improvement in the immature-mature cell ratio.³ It has been suggested also that the ratio of immature to mature neutrophils might be used in the control of vaccine therapy.^{1a, 1b} The present study was made to determine whether there might be changes in the ratio of young to old neutrophils which would correlate with the subjective responses which sometimes follow the injection of autogenous vaccines.

MATERIAL AND METHODS

Observations were made on a group of persons with low-grade chronic illness in whom chronic infection was considered to be an important factor. Detailed analyses of this group as to clinical condition, sedimentation rate, and nonfilament-filament ratio,² and incidence of probable pathogenic streptococci and staphylococci⁴ have been reported. Autogenous vaccines prepared from organisms isolated and selected by methods previously described^{4, 5} were administered subcutaneously in varying dilutions to these persons. At times following injection of the diluted vaccines there were definite subjective responses which could be reproduced by reinjection of the same doses of vaccine at appropriate intervals.

Blood smears were made at frequent intervals, sometimes several times daily when the sequence of changes was rapid, from persons in whom definite subjective responses were noted. Differential blood counts were made, neutrophils being divided into nonfilamented and filamented types (or nonsegmented and segmented types, no distinction being made between the two methods⁶), according to the criterion of Haden,⁷ i.e., "neutrophils in which two or more lobes are united only by a filament of chromatin material are recorded as filamented cells, all others are classified as nonfilamented." The ratio of nonfilamented to filamented neutrophils (referred to as "nonfilament-filament ratio") was expressed in percentage; i.e., nonfilament-filament ratio =
$$\frac{\text{nonfilamented cells} \times 100}{\text{filamented cells}}.^2$$

Received for publication, May 29, 1940.

RESULTS

To a large extent the changes in the nonfilament-filament ratio paralleled subjective changes, i.e., when symptoms were increased the nonfilament-filament ratio was increased, and when symptoms were lessened the nonfilament-filament ratio was lessened.

Three general types of subjective response to vaccine injection were noted, with corresponding nonfilament-filament ratio changes:

Type I: In the first type there was a period of definite lessening or cessation of symptoms, accompanied by a feeling of well-being, lasting from a few days to a week or more.

Fig. 1.—Variations in the nonfilament-filament ratio during a five-day control period and after two injections of vaccine which were followed by subjective improvement (type I response).

Fig. 2.—Variations in the nonfilament-filament ratio during a control period and after vaccine injections in a person who developed transient unfavorable symptoms (less than twenty-four hours) followed by definite improvement (type II response).

Type II: The second type of response was characterized by an initial period of increased intensity of illness, with malaise, depression, headache, or other general symptoms (the so-called negative phase), followed by a period of definite improvement. The negative phase lasted from a few hours to a few days, and the subsequent period of improvement from a few days to a week or more.

Type III: The third type was characterized by a prolonged negative phase, lasting a week or more, with little or no subsequent improvement. In this type

the unfavorable symptoms of the negative phase were usually milder in intensity and more delayed in onset than the unfavorable symptoms in type II responses.

In Figs. 1, 2, and 3 are shown typical examples of the nonfilament-filament ratio changes accompanying the different types of subjective response. In each instance there are included observations of the nonfilament-filament ratio made on each of the five days prior to the injection of vaccine, and the observations made subsequent to two injections.

Fig. 3.—Variations in the nonfilament-filament ratio during a control period and following vaccine injections in a person who developed prolonged unfavorable reactions with very little subsequent improvement (type III response). Note that following the second injection there was a delay of more than a day in the onset of the unfavorable change in the nonfilament-filament ratio.

Fig. 4.—Composite graph based on the means of the nonfilament-filament ratio observations in 28 persons who improved following vaccine injection (type I response).

Fig. 4 is a composite graph based on the means of the nonfilament-filament ratio observations at the time of injection, at the time of greatest improvement, and at the time of final observation, of 28 persons who improved following vaccine injection (type I response). The mean nonfilament-filament ratios were 26.75, 11.6, and 16.0, respectively. The separate graphs of the 28 persons are shown in Figs. 4A, 4B, and 4C.

Fig. 5 is a composite graph similarly based on the means of the nonfilament-filament ratio observations of 12 persons who experienced preliminary unfavorable symptoms following injection. In these persons the unfavorable reaction, which lasted from one to five days, was followed by a period of definite improvement (type II response). The mean of the nonfilament-filament ratios at the time of injection was 18.4; at the time of greatest increase in symptoms, 30.0;

Fig. 4A.

Fig. 4B.

Fig. 4C.

Figs. 4A, 4B, and 4C.—Separate records of nonfilament-filament ratios used in computing Fig. 4.

at the time of greatest improvement, 10.5; and at the time of final observation, 14.3. The separate curves of nonfilament-filament ratio change in the 12 persons are shown in Fig. 5A.

Fig. 5.—Composite graph based on the means of the nonfilament-filament ratio observations in 12 persons who, after vaccine infection, experienced preliminary unfavorable symptoms followed by definite improvement (type II response).

Fig. 5A.—Separate records of nonfilament-filament ratios used in computing Fig. 5.

Fig. 6 is a composite graph based on the means of the nonfilament-filament ratio observations of 8 persons in whom there was a prolonged unfavorable reaction (type III response). The mean of the individual nonfilament-filament ratios at the time of injection was 15.5; at the time of the most severe symptoms, 29.3; at the time of greatest improvement, 13.0; and at the time of final observation, 14.9. The separate graphs of the nonfilament-filament ratio changes of the 8 persons are shown in Fig. 6A. In this group of persons there was little, if any, subjective improvement following the prolonged unfavorable reaction, and the mean of the nonfilament-filament ratio observations at the time of greatest improvement was very little better than the mean of the original observations.

Providing there was no intercurrent illness, there were no significant non-filament-filament ratio variations observed in persons receiving no injections,

Fig. 6.—Composite graph representing the means of the nonfilament-filament ratio observations in 8 persons who experienced prolonged unfavorable reactions with little or no subsequent improvement (type III response) following vaccine injection.

Fig. 6A.—Separate records of nonfilament-filament ratios used in computing Fig. 6.

Fig. 7.—Nonfilament-filament ratios after injections of vaccine diluting fluid (0.5 per cent phenol) in 4 persons. Injections were made at the time of initial observation and were repeated as indicated.

e.g., during initial five-day periods (Figs. 1, 2, and 3), or in persons receiving injections either of diluting fluid (Fig. 7), or of vaccine too dilute to produce any subjective response (Fig. 8).

Fig. 8—Nonfilament-filament ratios of 4 persons in whom there was no evidence of subjective response following the injection of excessively diluted vaccine. (In Fig. 4C are shown the nonfilament-filament ratios of the same persons following the injection of stronger vaccines which produced type I responses.)

TABLE I

STATISTICAL ANALYSIS OF NONFILAMENT-FILAMENT RATIO CHANGES FOLLOWING THE INJECTION OF AUTOGENOUS VACCINES*

	NONFILAMENT-FILAMENT RATIO			
	NO	MEAN	S.D.	S.E.
Type I response				
Observations at time of injection	28	26.75	11.23	2.12
Observations during greatest improvement	28	11.57	4.60	0.87
Final observations	28	16.04	6.32	1.19
Type II response				
Observations at time of injection	12	18.42	4.31	1.30
Observations during most severe symptoms	12	30.08	12.29	3.72
Observations during greatest improvement	12	10.05	4.01	1.21
Final observations	12	14.25	2.97	0.895
Type III response				
Observations at time of injection	8	15.50	7.07	2.67
Observations during most severe symptoms	8	29.25	12.18	4.61
Observations during greatest improvement	8	13.00	4.34	1.64
Final observations	8	14.88	4.29	1.62

*No. indicates number of cases; S.D., standard deviation; S.E., standard error.

COMMENT

A statistical analysis of the nonfilament-filament ratio observations is presented in Table I. The differences between the means of the initial observations and the means of the observations at the point of most unfavorable symptoms were statistically significant (5.2 times the standard error in type II responses and 5.1 times the standard error in type III responses). Significant also were the differences between the means of the observations at the point of most unfavorable symptoms and at the point of greatest improvement (8.8 times the standard error in type II responses and 6.5 times the standard error in type III responses). The differences between the means of the initial observations and the means of the observations at the point of greatest improvement were statistically significant except in patients who experienced prolonged unfavorable

reactions (8.2 times the standard error in type I responses and 4.5 times the standard error in type II responses, but only 1.2 times the standard error in type III responses).

While in general the changes in the nonfilament-filament ratio paralleled the subjective changes, there were a few exceptions, probably because in these instances the symptoms might have been influenced by emotional, climatic, allergic, or other factors without corresponding changes in the leucocyte ratio.

SUMMARY

Nonfilament-filament counts were made at frequent intervals on persons showing definite subjective response to injections of antogenous vaccines. When there was an increase in symptoms, there was an increase in the nonfilament-filament ratio. When there was a lessening of symptoms, there was a lessening of the nonfilament-filament ratio. The variations in the nonfilament-filament ratio were statistically significant.

STUDIES ON ANTIPNEUMOCOCCIC RABBIT SERUM*

I. THE CORRELATION BETWEEN THE THERMAL REACTION TEST IN THE RABBIT AND THE INCIDENCE OF CLINICAL REACTIONS IN PNEUMONIA PATIENTS

TILLMAN D. GERLOUGH, B.S., REUBEN R. BLUMENTHAL, PH.D., AND
JOHN W. PALMER, PH.D., NEW BRUNSWICK, N. J.

SABIN and Wallace¹ described a test for the presence of chill-producing substances in concentrated antipneumococcic horse serum in which dogs were injected intravenously with the serum. A rise in rectal temperature of 1.5° F. or more in about an hour indicated sufficient chill-producing material to cause reactions in patients treated with the serum. Barnes and Robinson,² using monkeys in a similar test, did not obtain as good agreement between their laboratory and clinical results.

Goodner, Horsfall, and Dubos³ have correlated thermal reactions produced in rabbits with incidence and severity of chill or febrile reactions in pneumonia patients when both were injected intravenously with the same antipneumococcic rabbit serum. They state that if the mean rise in temperature of a group of rabbits, each of which receives 2.0 ml. of serum, exceeds 1.2° F., the serum will produce chills in patients, and if the mean rabbit thermal reaction is over 2.0° F., the serum will produce such severe chills that it should not be used clinically. In their experience sera producing a thermal rise in rabbits of less than 1.2° F. gave no chills in patients. It was emphasized that the correlation was established only for sera prepared and processed by their procedure. Their sera were not concentrated but were treated with heat and kaolin.

It was desirable to know whether or not any such relationship existed in the case of concentrated antipneumococcic rabbit serum. During the development of refining and concentrating procedures for rabbit serum, more than 20 lots of concentrated serum were subjected to both clinical and rabbit tests, and a good degree of correlation was found.

Table I records the data. The rabbits employed for thermal tests were selected as follows: On the day of the test the rectal temperatures were taken. Animals with a normal temperature greater than 103.6° F. were not used. One milliliter of a freshly prepared pyrogen-free 0.9 per cent sodium chloride solution containing 0.2 per cent phenol and 0.01 per cent merthiolate was then injected intravenously, and the rectal temperature was taken at the end of one hour. If at this time the temperature had not varied more than 0.6° F. from its normal, the animal was then used for the thermal test of the serum.

*From the Biological Laboratories of E. R. Squibb & Sons, New Brunswick.
Received for publication, May 28, 1940.

Routinely 1.0 ml. of the concentrated serum was injected into an ear vein of a rabbit in one minute. (This dose is of the same order as that employed by Goodner, Horsfall, and Dubos with respect to the amount of protein administered.) The temperature was read one hour and two hours after the injection. The temperature difference at the one-hour interval was taken as the most significant, and has been used in the tabulations.

†Probable error = $0.6745 \sigma / \sqrt{n}$, where σ is the standard deviation and n is the number of rabbits used to test the lot of serum.

‡Calculated from antibody nitrogen.*

Five to 8 rabbits were used for each routine test. In many instances the test was carried out on the concentrates before and after sterile filtration. No significant differences were found in the two samples. All samples tested prior to sterile filtration were passed through a small Seitz E.K.S-3 asbestos pad to remove dust, lint, and other insoluble matter.

The potency of the antisera for types I, II, V, VII, and VIII pneumococci was determined by comparison in mouse protection tests with the standard sera distributed by the National Institute of Health. The sera for types III and IV were standardized in terms of Felton mouse protective units as determined in our laboratories, there being no official standard sera for these types. The

Fig. 1.

type XIV antiserum was evaluated by the quantitative precipitin reaction,⁴ 1 mg. of specifically precipitable antibody nitrogen representing 750 units, as recommended by the National Institute of Health.⁵

The clinical data are taken from reports received from 24 physicians located in various parts of the country.

Inspection of Table I reveals, for most lots, a definite relationship between the laboratory rabbit test and clinical observation. There is, of course, some dispersion which is particularly evident with lots for which only a few clinical reports were received.

The reports show that an average of 170,000 units of antibody was administered to each patient. In general, the chill or febrile reaction, when produced, occurred after the first large dose of about 50,000 units. Subsequent injections of the same serum were, for the most part, uneventful. Chills were usually severe if produced by a concentrated serum which caused a rise of 1.5° F. or more in rabbits. Potency or type of serum apparently had no significance as far as reactions were concerned.

It is not known what substance or substances in rabbit serum cause the thermal or chill reaction. In the statistical treatment of the data, it was assumed that the reactions were due to the same general type of pyrogenic substance which varied in amount from lot to lot. The thermal rise in rabbits was taken as a measure of the concentration or dose of pyrogenic material, and the incidence* of chill reactions in patients as an expression of the effect. This dose-effect relationship probably follows a typical sigmoid curve.

The data were plotted on arithmetic probability paper, and the percentage incidence of chill reactions was converted into probits.⁶ The weighted correlation coefficient† between the thermal rise in rabbits (in degrees Fahrenheit) and the probit values of percentage incidence of reactions in patients is 0.84, based on 193 patients and 292 rabbits treated with 21 lots of serum. In view of this high degree of correlation, a prediction equation was calculated. This equation is

$$I = 1.821T + 2.835,$$

where I is the probit value of the percentage incidence and T is the thermal rise in rabbits. Column 7 of Table I shows the value for incidence of chills as predicted by the above equation. The weighted average percentage deviation‡ of the observed from the calculated values is ± 7.0 per cent of the calculated values.

The sigmoid curve in Fig. 1 is a calculated weighted curve transposed from the regression line obtained on arithmetic probability paper, and is, therefore, a graphic expression of the prediction equation given above.

SUMMARY

A high degree of correlation (0.84) has been found between the temperature rise produced in rabbits and the incidence of chill reactions in patients with pneumonia following the administration of concentrated antipneumococcal rabbit serum.

An equation was developed permitting the prediction of incidence of chill reactions, the weighted average deviation of the calculated from the observed values being ± 7.0 per cent.

We wish to express our appreciation to Mr. H. A. Holaday and his associates of the Biological Assays Laboratories for carrying out the thermal tests in rabbits, and to Dr. G. F. Leonard and Dr. August Holm of the Bacteriological Laboratories for the mouse protection potency tests.

*Incidence is defined here as the percentage of patients treated with a given serum who developed a chill or chills. In general, the chill reaction was accompanied by a rise in temperature.

†Weights were assigned each observation in proportion to the number of patients treated with each lot of serum.

SPECIFIC CHEMOTHERAPY OF GIARDIA INFECTIONS*

JAMES T. CULBERTSON, PH.D., NEW YORK, N. Y.

ALTHOUGH many widely different chemotherapeutic agents had been tried previously in the therapy of giardiasis, no effective drug was available until recent years for the permanent elimination of the giardias from man and animals. In 1937 Brumpt,¹ working with mice infected with *Giardia muris*, found that the administration by mouth of a 1 per cent solution of "quinacrine" (the French equivalent of atabrine) permanently cured 80 per cent of the infections. Later in the same year, Galli-Valerio² reported the successful elimination of *Giardia lamblia* from man by the administration of atabrine. A number of papers³ have since confirmed these first observations, and atabrine seems now fairly well established as an effective and safe drug for the treatment of giardiasis. The present communication offers further evidence upon the action of atabrine upon giardia infections of man, and of the albino rat and mouse.† The paper reports also that acriflavine, another acridine derivative, likewise is an effective drug in giardia infections of animals.

ATABRINE IN GIARDIA INFECTION OF MAN

Two cases of *Giardia lamblia* infection of man have been treated with atabrine. The first of these concerned an individual in whom the extraordinary persistence of the parasite has previously been reported by Miles and myself.⁴ Because this case responded so promptly to atabrine therapy, permanent cure being effected by a single course of treatment, the use of the drug in it will be described in some detail. The second human case, of which much less is known, will be only briefly mentioned.

Cure by Atabrine of a Long-Persisting Giardia Infection in Man.—The patient was a young woman of about 25 years of age, whose infection had been first

*From the Department of Bacteriology, College of Physicians and Surgeons, Columbia University.

Received for publication, May 29, 1940.

†The atabrine used in the work was supplied by the Wmthrop Chemical Co., New York, N. Y.

diagnosed approximately six years earlier. At irregular intervals since the initial observation, the parasites or their cysts had been found in the patient's stools, search being made at least once each year and during some years frequently. An ineffectual attempt was made in the summer of 1936 by an attendant physician to eliminate the parasites by administering carbarsone. Cysts of the parasite were believed reduced in number thereafter for a time, but they never entirely disappeared. Soon after the cessation of treatment, they became as numerous as they had been originally.

Cysts of the parasite were observed in large number in January, 1940, one day prior to the institution of treatment with atabrine. Atabrine treatment was begun under the direction of Dr. C. W. Jungeblut of this department, two 0.1 Gm. tablets being given daily for five days. A stool specimen obtained two days after the last day of treatment was negative for cysts and trophozoites of *Giardia lamblia*, prolonged search being made of repeated samples of stool. Likewise, when stools obtained one, two, four, and six weeks later were examined, no cysts or trophozoites of *Giardia lamblia* could be found.

No significant by-effects of treating the patient with atabrine were noted. On the last day of treatment the patient felt listless and sneezed occasionally, but these symptoms were not certainly related to the use of the drug. No pigmentation of the skin was observed at any time. One day after the cessation of treatment, the stool was said by the patient to be somewhat watery and of a bright yellow hue, but subsequent stools were normal.

Cure by Atabrine of a Second Case of Human Giardiasis.—A second case of giardiasis in man was also treated successfully with atabrine, the drug being administered by Dr. H. M. Rose of this department. A stool examined just prior to the institution of treatment revealed many cysts of *Giardia lamblia*. Two 0.1 Gm. tablets of atabrine were given daily for five days. Stools obtained for three successive days after the last day of treatment were examined carefully, but neither cysts nor trophozoites of the parasite were seen. This patient has not since returned for observation.

ATABRINE IN GIARDIA INFECTION OF ALBINO RATS

Thirty rats naturally infected with *Giardia muris* were used to test the therapeutic action of atabrine upon giardiasis of rats, the infection being proved to exist in each rat by finding cysts of the parasite in a saline suspension of feces of the animal. All rats were small when used, weighing about 30 Gm. Atabrine in water solution was administered by mouth to 20 of the infected animals on two successive days, each dose being 10 mg. per 30 Gm. body weight. The drug was given by syringe through a blunted hypodermic needle (size 22; 1.5 inch length) lowered carefully into the pharynx or esophagus. The 10 remaining infected rats received no drug at any time, and were kept as controls of the infection in cages separate from the treated rats. The feces of the treated and control animals were examined daily for one week after the last dose of the drug. All the treated animals were free of the parasite, so far as fecal examination revealed by the first day after treatment, and remained so during the ensuing week (Table I). The 10 control rats retained their infections throughout this

period. Twelve of the treated rats were kept for three additional weeks, and their feces were examined at weekly intervals during this period. No animal revealed giardia cysts at any examination. At the end of this time these 12 rats were autopsied, and the small intestine was searched for trophozoites of *Giardia muris*. None was seen in any animal. It appears from this work that *Giardia muris* is promptly removed from the intestine of albino rats by the administration of 10 mg. of atabrine per 30 Gm. of rat body weight daily for two days, and that infections so treated do not relapse, at least during one month following treatment.

TABLE I

EFFECT OF ATABRINE AND OF ACRIFLAVINE UPON *GIARDIA* INFECTIONS IN DIFFERENT HOSTS

GIARDIA SPECIES	HOST SPECIES	DRUG USED	TOTAL DOSE OF DRUG GIVEN	NO. HOSTS TREATED	NO. HOSTS CURED	PERIOD OF OBSERVATION AFTER TREATMENT	UNTREATED CONTROLS	
							NO. USED	NO. POSITIVE FOR AT LEAST ONE WEEK
<i>Giardia lamblia</i>	Man	Atabrine	1 Gm.	2	2	3 days: 6 weeks	None	-
<i>Giardia muris</i>	Rat	Atabrine	20 mg.†	20	20	1 week to 1 month	10	10
<i>Giardia muris</i>	Mouse	Atabrine	20 mg.†	10	10	1 week	5	5
<i>Giardia muris</i>	Rat	Acridiflavine	20 mg.†	10	10	1 week	5	5

*One of the human cases was positive for over five years prior to treatment.

†Per 30 Gm. body weight.

It should be added that the rats tolerated the atabrine very well, and no animal was lost during the course of the experiment. The dose was, however, large in proportion to that given to the patients described earlier, and all the treated animals presented yellow pigmentation of the skin on the day after the second dose of drug was given. The pigment persisted for one week, and in some cases for longer periods. In several other rats given this dose of atabrine and autopsied one or two days thereafter, the small intestine was found deeply stained with the color of atabrine, particularly in those parts where *Giardia muris* is most commonly found.

ATABRINE IN *GIARDIA* INFECTION OF ALBINO MICE

Fifteen mice, all known from fecal pellet examination to harbor *Giardia muris*, were used to test the effect of atabrine upon mouse giardiasis. Ten animals were given 10 mg. of atabrine by mouth per 30 Gm. body weight on each of two successive days in the same manner as previously described for the infected rats. The remaining 5 mice were kept as controls for the natural persistence of the infection in the absence of treatment. The feces of all animals were examined daily for the presence of cysts of the parasite for one week, beginning one day after the last dose of drug. All treated mice were free of the infection, so far as fecal examination revealed, by the first day after treatment, and remained so throughout the period of observation (Table I). Autopsy at the end of this interval revealed no trophozoites of the parasite in the small intestine. The control mice showed cysts of the parasite in the feces at each of the daily observations until autopsy and then revealed the trophozoite stage in

the intestine. Apparently, cure of giardia infection by the administration of atabrine is about as successful in the mouse as it is in the rat or in man.

ACRIFLAVINE IN GIARDIA INFECTIONS IN ALBINO RATS

The remarkable effect obtained with atabrine upon the different giardiasis led to the trial of other acridine derivatives. One of these, acriflavine, a simpler substance than atabrine,* was also found to act powerfully upon giardiasis in the albino rat. This experiment was performed upon 15 albino rats, all proved by fecal examination to harbor *Giardia muris* prior to treatment. The same dose of acriflavine as that used with atabrine (10 mg. per 30 Gm. of body weight on two successive days) was given by mouth to 10 animals, the remaining 5 rats serving as controls. On the first day after treatment and throughout the week following, fecal examination revealed no cysts of *Giardia muris* in the treated animals, although the control rats continued to harbor the parasite throughout this period (Table I). At autopsy one week after treatment, no trophozoites of the parasite were found in the small intestine of the 10 treated animals. From this work it appears that acriflavine is an effective giardicide. It should be pointed out, however, that the drug in the dose used appeared to harm the rats, for, although none died, all lost weight.

TABLE II

EFFECT OF ATABRINE AND ACRIFLAVINE ON VARIOUS INTESTINAL PROTOZOA OF RATS

DRUG USED IN TREATMENT	NO. RATS IN GROUP	PERCENTAGE OF RATS HARBORING DESIGNATED PROTOZOA AT AUTOPSY					
		<i>Giardia muris</i>	<i>Hexamita muris</i>	<i>Chilomastix bettencourti</i>	<i>Trichomonas muris</i>	<i>Trichomonas parva</i>	<i>Endamoeba muris</i>
Atabrine	15	0	14	33	53	67	28
Acriflavine	11	0	9	72	45	72	27
None	23	21	30	65	60	73	56

Dose of drug: 10 mg. per 30 Gm. body weight daily for two days.

Autopsy was performed two days after last dose of drug.

EFFECT OF ATABRINE AND OF ACRIFLAVINE UPON CERTAIN INTESTINAL PROTOZOA OTHER THAN GIARDIA MURIS IN ALBINO RATS

An experiment was designed to test the effect of atabrine and of acriflavine upon certain intestinal protozoa other than *Giardia muris* found in albino rats. For this work, 49 rats of five different litters were used. The feces of these animals were not examined prior to treatment, but part of each litter was kept untreated as control. Fifteen rats were given atabrine and 11 were given acriflavine in the same dosage previously described (10 mg. per 30 Gm. body weight on two successive days); 23 rats received no drug treatment. Two days after the last dose of the drugs, all treated rats and controls were killed and their intestine searched for *Trichomonas muris*, *Trichomonas parva*, *Chilomastix bettencourti*, *Hexamita muris*, and *Endamoeba muris*, as well as for *Giardia muris*. In the case of none of the forms except *Giardia muris* was evidence forthcoming that either atabrine or acriflavine was regularly effective as a destructive agent, although in some instances the relative intensity of infection

*Atabrine: 2-methoxy 6-chloro 9-diethyl amino pentylamino acridine.
Acriflavine: 3, 6-diamino-acridinium-methyl chloride.

in the treated animals appeared somewhat less than in the control rats (see Table II). Of special interest was the persistence of *Hexamita muris* in the treated rats, since this parasite is closely related with *Giardia muris*. This experiment indicated that of the several species of protozoans found in the intestine of the albino rat atabrine and acriflavine exhibit a selective action upon giardia alone.

DISCUSSION

It is obvious from the data given in this paper, as well as from that of a number of other investigators who have previously studied the same problem, that atabrine is an effective drug for the cure of giardia infections of man and animals. Apparently, the giardias can now be placed with a slowly but constantly increasing list of parasites which are subject to control and elimination through the administration of specific chemical substances to the infected individual.

Atabrine appears to be a more favorable drug than acriflavine to use in the elimination of the giardias, judging from the experiments with *Giardia muris* of the rat, for rats treated with an equivalent dose of acriflavine lost weight and usually contracted respiratory infections, whereas those given atabrine showed none of these effects. Nevertheless, acriflavine was as effective as atabrine so far as the elimination of the parasite from the host was concerned.

The discovery of a drug which effectively cures giardia infections in man should render more soluble the old problem of the pathogenicity of *Giardia lamblia* in man. If the parasite is eliminated by atabrine treatment, then symptoms resulting directly from giardia infection should promptly disappear after treatment. On the other hand, if *Giardia lamblia* is not the cause of such symptoms, elimination of the parasite by atabrine cannot be expected to modify these symptoms. In one of the human cases reported in this paper, which was followed for a long period both before and after atabrine treatment, symptoms (epigastric pain, intestinal upset) were unchanged by the drug treatment. Evidently, the presence of the giardias was not responsible for the symptoms in this human case.

SUMMARY

Giardia parasites can be easily eliminated from man, and from albino rats and mice by the administration of atabrine. Apparently the infections are permanently cured by the drug, for relapses following treatment have not been observed in two human infections, one of which was carefully observed during six weeks thereafter, or in infections of laboratory animals which were followed for shorter periods. Reappearance of giardia parasites after treatment would seem, therefore, to occur only as the result of an exogenous reinfection contracted after the force of the drug were spent. The cure of the infection is rapid, no giardia cysts being seen even as early as the first day following the last dose of the drug in patients or in laboratory animals. Of especial interest is the fact that a single course of treatment sufficed to cure, presumably permanently, one of the human cases which had persisted previously for over five years.

Acriflavine, another acridine derivative, likewise will cause the disappearance of *Giardia muris* from the albino rat, although this drug seems less well tolerated by the animal than atabrine.

Neither atabrine nor acriflavine in the dose given to cure giardia infections is effective in eliminating infections with *Trichomonas muris*, *Trichomonas parva*, *Chilomastix bettencourti*, *Hexamita muris*, or *Endamoeba muris* from the albino rat.

I wish to thank Dr. C. W. Jungeblut and Dr. H. M. Rose, of this department, for their cooperation in this study.

STUDIES OF THE EFFECT OF INTRAVENOUS ADMINISTRATION OF LIVER EXTRACT IN PATIENTS WITH SICKLE-CELL ANEMIA: AN UNUSUAL RESPONSE*

GEORGE VRYONIS, M.D., NASHVILLE, TENN.

A STUDY was undertaken to follow in detail the results of liver extract administered intravenously to patients with sickle-cell anemia.

MATERIAL AND METHODS

Four patients with sickle-cell anemia were studied. The blood was examined for ten to fifty days to establish the range of spontaneous variations. Twenty cubic centimeters of liver extract were administered intravenously, and daily counts were made of both white and red blood cells and reticulocytes for fifteen to forty days. In Case 4 (Fig. 1) additional counts were made at twenty minutes, three hours, five hours, and twelve hours following the administration of liver extract.

CASE 1.—T. P., 3 years old, was admitted with pains in the feet and ankles and with mild rhinopharyngitis. X-rays showed marked general cardiac enlargement and osteoporosis of the skull and long bones. Kahn and Wassermann tests were negative. Cholesterol was 110.3 mg. per 100 c.c. of blood, erythrocytes were 2,000,000 per c.mm. with 30 per cent reticulocytes, or 600,000 per c.mm., leucocytes were 10,000 per c.mm. with differential per cent as follows: lymphocytes 35.5, polymorphonuclear cells 54.5, mononuclear cells 6.0, eosinophiles 2.5, basophiles 0.5, and unidentified cells 1.0. Nucleated red blood cells and numerous sickle-cells were present. The blood count was not influenced by the liver extract.

*From the Department of Medicine, University of Georgia School of Medicine, Augusta.
Received for publication, May 31, 1940.

CASE 2.—W. M. J. was admitted with a leg ulcer of three years' duration and primary syphilis. Electrocardiogram showed slight myocardiac damage. Kahn test of blood was positive. Cholesterol was 139.13 mg., sugar 100 mg., nonprotein nitrogen 28.5 mg per 100 c.c. of blood. Erythrocytes were 1,900,000 per c.mm. with 22 per cent reticulocytes, or 418,000. Leucocytes were 25,000; differential per cent: lymphocytes 16.0, neutrophils 61.0, eosinophiles 15.0, monocytes 8.0. Volume index was 1.10. The patient was receiving weekly injections of neocarsphenamine while under observation. The blood and clinical course were not influenced by the administration of liver extract.

FIG. 1.—Chart showing leucocytes, erythrocytes, and reticulocytes per cubic millimeter and absolute number of the different types of white blood cells in relation to treatment (Case 4, R. R.).

CASE 3.—A. K., 38 years old, was admitted with joint pains and history of similar attacks in the past. He had received antisyphilitic treatment. On February 27 the icteric index was 7.7. Calcium was 9.4 mg., cholesterol 118.5 mg., uric acid 3.7 mg., organic phosphorus 3.6 mg., sugar 91.0 mg., nonprotein nitrogen 27.5 mg. per 100 c.c. of blood. On March 2 bilirubin was 4.16 mg. per 100 c.c. of blood; icteric index was 8.0. Erythrocytes 4,000,000 with reticulocytes 16 per cent, or 640,000 per c.mm. Nucleated erythrocytes were 5,140 per c.mm. Leucocytes were 18,000; differential per cent: lymphocytes 31.0, polymorphonuclear cells 54.0, eosinophiles 3.0, basophiles 2.0, monocytes 10.0. The administration of liver extract did not influence the blood picture.

CASE 4.—R. R., aged 14 years, was admitted with a leg ulcer. He had been admitted 12 years previously during an abdominal crisis. On previous admission (Sydenstricker) he had 1,541,000 erythrocytes with 34 per cent reticulocytes, or 524,000 per c.mm. Leucocytes were 20,000. During present admission his count was erythrocytes 2,300,000 with 18 per cent reticulocytes, or 414,000 per c.mm. Leucocytes were 16,000; differential per

lymphocytes 44.0, neutrophils 48.0, eosinophils 3.0, basophils 1.0, monocytes 4.0. Numerous sickle cells and few nucleated erythrocytes were found. Volume index was 110-118. Three hours after liver extract was administered, leucocytes showed an increase and maintained this rise for nine days. The erythrocytes rose on the third day, and the reticulocytes showed a definite rise on the fifth day. The rise was progressive for all three elements, and on the seventh day they all reached the peak: erythrocytes 3,800,000 with 32 per cent reticulocytes, or 1,200,000 per c.mm. and leucocytes 33,000. On the ninth day the blood count returned to the level noted before treatment. The rise of leucocytes was due entirely to the increase of mature polymorphonuclear cells. The proportion of sickle cells was practically unaltered. The hemoglobin rose, but not in proportion to the rise of the erythrocytes. On the day of administration hemoglobin (Sahli) was 48.0 per cent with 2,300,000 red blood cells; on the fifth day hemoglobin was 66 per cent with 3,555,000 erythrocytes. It returned to the previous level simultaneously with the erythrocytes. Twenty-three days later the same dose of liver was repeated, and on the eighth day a moderate rise of polymorphonuclear cells was observed up to 24,000 per c.mm.; this rise lasted three days. On the eleventh day the erythrocytes rose for two days, but there was no rise in reticulocytes (Fig. 1).

DISCUSSION

Sydenstricker² pointed out that the treatment of sickle-cell anemia is most unsatisfactory. Diggs³ published charts illustrating the negative results in the treatment of sickle-cell anemia by liver extracts.

Following intravenous injection of liver extract, Meyer, Middleton, and Theulis⁴ found depression of leucocytes within twenty minutes in normal persons and in patients with blood dyscrasias; this depression was followed by a leucocytosis which reached the maximum three hours later. Miller and Rhodes,⁵ in an anemic woman with splenomegaly, found increase of leucocytes in twenty minutes, as well as an increase in the other formed elements of blood, with return to normal in twenty-four hours; the rise of blood count was simultaneous with contraction of the spleen.

The case of R. R. seems to be unique in its response to liver extract. The rise of erythrocytes before the increase in reticulocytes is different from that observed in pernicious anemia. The volume index was slightly higher than normal, but this is frequent in cases of sickle-cell anemia when the reticulocytes are high. The spleen was not palpable and was thought to be greatly diminished, as in sickle-cell anemia. No abnormal blood pressure changes were noted on the day of administration or later. The independent appearance of the rise of leucocytes and erythrocytes, and the duration of this rise, exclude the possibility of its being the result of any kind of redistribution. I feel compelled to consider it the result of action on the hematopoietic system, although the previous administration of liver by mouth and of liver extract intramuscularly was without effect.

SUMMARY

1. The results of the intravenous administration of liver extract to 4 patients with sickle-cell anemia are reported, with 3 patients showing no response and one patient showing unusual response of the hematopoietic system.
2. This response consists in the increase of polymorphonuclear leucocytes, erythrocytes, and reticulocytes on the first, third, and fifth days, respectively, with simultaneous return to previous level on the tenth day.
3. This is considered as the result of action of the extract on the hematopoietic tissue.

STUDIES IN BLOOD PRESERVATION*

FATE OF CELLULAR ELEMENTS AND PROTHROMBIN IN CITRATED BLOOD

CHARLES R. DREW, M.D., AND JOHN SCUDDER, M.D.
NEW YORK, N. Y.

IN A previous article² we reported the changes observed in blood preserved with heparin. The results presented in this study are typical of a large number of observations on citrated blood.

METHOD

Five cubic centimeters of freely flowing venous blood were collected in each of thirty-five sterile flat-bottomed tubes containing 0.5 c.c. of 3.5 per cent sodium citrate solution as the anticoagulant. The blood was kept in a refrigerator at a temperature of from 4° to 6° C. throughout the period of the experiment.

Each day one tube was taken from the refrigerator and the following determinations were made: red blood cell count, hemoglobin, white blood cell count, differential white blood cell count, platelet count, and fragility test.

The plasma clotting time was done on two samples of 50 c.c. of blood by the method of Quick,^{7,8} who postulates that the rate of coagulation is a function of the concentration of prothrombin, and the production of thrombin in oxalated plasma is proportional to the concentration of prothrombin if an excess of thromboplastin is present and an optimal amount of calcium is added. The plasma was recalcified with calcium chloride at a constant temperature of 40° C. in the presence of human brain tissue emulsion to supply the thromboplastin substance, the end point being recorded by the shift on a photoelectric cell galvanometer.

This study was made possible by a grant from the Blood Transfusion Betterment Association, New York.

Received for publication, June 1, 1940.

RESULTS

Donor, W. T. S.

COMPARATIVE VALUES OF BLOOD IN HEPARIN AND IN SODIUM CITRATE

	HEPARIN	SODIUM CITRATE 0.35 PER CENT
Hematoerit (3)	48.5	42.3 per cent cells
Plasma specific gravity (3)	1.0249	1.0238
Plasma proteins (3)	6.12	5.75 Gm. per cent
Whole blood potassium (10)	192.0	183.0 mg. per cent
Plasma potassium (10)	17.5	17.2 mg. per cent
Cell potassium (calculated) (10)	377.0	409.0 mg. per cent

VALUES ON INITIAL SAMPLE CORRECTED FOR DILUTION IN CITRATE

Red blood cell count	5,100,000.0
Hemoglobin	15.6 Gm. per cent
White blood cell count	7,700.0
Differential white blood cell count	
Polymorphonuclear leucocytes	61.0 per cent
Lymphocytes	29.0 per cent
Monocytes	7.0 per cent
Eosinophilic leucocytes	2.5 per cent
Basophilic leucocytes	0.5 per cent
Platelets	206,800.0

The results of the counts and hemoglobin determinations are graphically represented in Figs. 1, 2, and 3.

Fragility of Erythrocytes.—The end points were poor throughout these studies. An actual curve of fragility could not be constructed on a daily basis. As late as the fifteenth day cells could be suspended in 0.45 per cent sodium ehloride without complete hemolysis. Even on the thirtieth day cells carefully handled did not lake completely in 0.52 per cent sodium ehloride.

Spontaneous hemolysis was first noted on the seventeenth day. Slight shaking in physiologic saline after the tenth day caused hemolysis. The cells on the tenth day are slightly less resistant than those on the first, and those stored for thirty days are definitely more fragile than those stored for ten days.

Prothrombin.—In the first series plasma clotting times were run for a period of fifty-two consecutive hours at one-hour (toward the end, two-hour) intervals. This was done with the aid of Dr. Kenneth Olsen. There was a rapid rise in clotting times in the first fifteen hours; at the end of this period the prothrombin content had been reduced to ineffectual levels. The curve was similar to that later published by Rhoads and Panzer⁹ and seemed to indicate that bloods stored for periods longer than a day would be ineffectual in treating hemorrhage which resulted from a deficiency of prothrombin.

Eight-day-old blood, however, was given a jaundiced patient with a hemorrhagic tendency, and bleeding stopped. This was reported to Dr. Olsen who made up a new extract of rabbit brain and repeated these tests on blood supplied to him from the blood bank. To his surprise this time there was no sudden loss of prothrombin concentration.

Through the courtesy of Dr. Grant Sanger we have been able to obtain the observations tabulated in Table I on separate bloods, each time being very careful to use fresh brain extract.

CELLULAR CHANGES IN CITRATED BLOOD

Fig. 1.—Red blood cell counts, corrected for dilution, varied between 5.5 and 4.6, the mean being 5.1 millions. Here there is an actual loss of 1,000,000 to 1,500,000 cells at the end of thirty days. Hemoglobin values varied between 13.6 and 16.3 Gm. per cent. The gradual rise is attributed to evaporation. Platelets fell from 206,800 to 87,800 in forty-eight hours, then remained constant for about fifteen days, after which time counts were difficult.

CELLULAR CHANGES IN CITRATED BLOOD

Fig. 2.—The total white blood cell count as observed in the chamber fell 27 per cent in the first five days. Careful differentiation of cells in the chamber and observation on a slide showed that 75 per cent of the total had no nuclei or were so fragile that they broke and left only a smudge by the twelfth day.

DISCUSSION

Red Blood Cells.—The maintenance of total erythrocyte counts at an approximately constant level in heparinized blood² and the moderate destruction of erythrocytes in citrated blood after the fifteenth day of storage suggest that cell destruction plays, at most, only a small part in the steady increase of the potassium content of the plasma,¹¹ and insures the recipient of receiving a large percentage of functioning cells after periods of storage of at least a month.

Fig. 3.—The nucleated leucocytes, presumably the only ones capable of function, decreased nearly 50 per cent in the first three days. The polymorphonuclear leucocytes diminished 50 per cent in twenty-four hours, accounting almost completely for the drop in total count. By the sixth day it was difficult to be sure that any remained. Eosinophiles were well preserved. Lymphocytes remained almost constant. Monocytes were difficult to differentiate.

Hemoglobin.—The hemoglobin content of the whole blood remains constant, though at the end of thirty days 20 per cent of it may be found in the plasma.

White Blood Cells.—The polymorphonuclear leucocytes may show swelling, hazy cytoplasm, and poorly staining nuclear granules as early as twenty-four hours after storage. Disintegration is extremely rapid and may be responsible for the steep rise of the potassium curve in the first week;¹¹ likewise it may play a part in decreasing bactericidal properties.^{4, 5}

The lymphocytes are more resistant. At the end of thirty days they are easy to recognize when seen.

The eosinophiles are most resistant, the eosinophilic granules remaining particularly bright even when the nuclear material has faded or broken up.

Platelets.—Platelets disintegrate more rapidly in heparinized blood² than in citrated blood. In both bloods they reach their low point in about three to five days. Platelets remaining stay fairly fixed until clumping makes counting difficult about the fifteenth day.

TABLE I
PROTHROMBIN CONCENTRATIONS IN PLASMA OF STORED BLOOD

DATE BLOOD STORED	DATE TEST MADE	AGE IN DAYS	PROTHROMBIN CONCENTRATION (PER CENT)
10/27/39	2/21/40	117	47
10/27/39	2/21/40	117	38
11/20/39	2/21/40	94	41
12/15/39	2/21/40	69	49
1/31/40	2/21/40	21	52
2/28/40	3/12/40	13	100
3/ 1/40	3/12/40	11	100
2/16/40	2/26/40	10	68
2/23/40	3/ 1/40	8	84
2/23/40	3/ 1/40	8	84
2/26/40	3/ 5/40	8	60
3/ 4/40	3/12/40	8	100
3/ 4/40	3/12/40	8	80
3/ 4/40	3/12/40	8	100
2/19/40	2/26/40	7	100
2/19/40	2/26/40	7	76
2/23/40	2/29/40	6	100
2/23/40	2/29/40	6	100
2/16/40	2/21/40	5	74

Prothrombin.—The results using the Quick method of determining the prothrombin concentration yield values similar to those reported by Lord and Pastore⁶ using the Brinkhous, Smith, and Warner method.¹ This suggests that the use of brain extract, which has been kept too long, may account for the discrepancy between reported findings. Dr. Olsen deserves credit for making this very essential observation.

SUMMARY

1. In citrated blood there is some loss in the number of red blood cells beginning about the fifteenth day and amounting to from 1,000,000 to 1,500,000 cells by the end of the month.
2. The hemoglobin content remains constant in the total sample, although 15 to 25 per cent may diffuse out of the cells into the plasma in one month.
3. The polymorphonuclear leucocytes are diminished to 50 per cent in forty-eight hours and are amorphous masses in fifteen days.
4. The lymphocytes and eosinophiles do not disintegrate so rapidly; the latter are particularly well preserved. The monocytes are difficult to trace.
5. The platelets fall rapidly to a level ranging from 50,000 to 80,000 and remain at this level for about fifteen days, at which time counts become difficult to make.
6. The fragility of red blood cells slowly increases with increasing age; exact curves are difficult to establish.
7. The prothrombin level is maintained above 40 per cent of normal concentration for a period of at least four months. The use of old brain extract

will cause clotting times which are too rapid, thereby giving a false picture of the true degree of efficacy of preserved blood in the therapy of hemorrhagic diseases associated with low prothrombin concentrations.

We are indebted to Miss Hildegard Menzel for aid in the prothrombin determinations and to Mr. Josiah Lasell for many hematologic studies.

EFFECT OF VITAMIN C ON WORKERS EXPOSED TO LEAD DUST

S. W. MARCHMONT-ROBINSON, Sc.B., M.D., CHICAGO, ILL.

THE present study deals with a group of 303 regular employees, 80 per cent of whom have been in their present place of occupation for five years, and the balance for a longer period. These men are engaged in various types of work in the assembly of passenger automobiles.

The lead exposure in this work of assembly arises from the practice of covering body seams with solder (60 per cent lead), and grinding off the excess metal to form a flush surface. There is thus thrown into the air a large quantity of lead dust which is of variable particle size, the majority of particles being too large to be inhaled.

In a large series of air samples it was determined by standard methods that there was a variable concentration along the assembly line of inhalable lead dust (10 microns or less in size). This concentration varied from 3 to 15 mg. per 10 cubic meters of air.

The concentrations of dust and the particle size findings coincide with the report of Humberdine¹ on similar lead hazards in European automobile assembly plants.

Provision for ventilation consists of overhead and floor level exhaust ducts; and grinders and metal finishers are furnished with daily inspected respirators. Floors are kept clean by wet sweeping.

Since early in 1935 all men who were even remotely in contact with lead dust have been examined physically, and a basophilic aggregation count was made (McCord)² once a month, or oftener if complaints arose.

During the period in 1935 in which a wave of hysteria concerning lead poisoning was at its height, there were 340 definite complaints that ranged from abdominal cramps, nausea, and vomiting, to alleged weakness of the extensor muscles of the wrists and forearms. The majority of these illnesses were patently of psychologic origin, but there were 13 men in this group who were hospitalized for further observation and possible treatment for lead intoxication.

Urinalysis for lead, both before and after deleading treatment, failed to show an abnormal excretion of lead in any one of these 13 men; and the basophilic aggregation count, with the exception of three of the group, did not bear out a diagnosis of lead intoxication.

The three men who had a high basophilic aggregation were variously found to have a severe pyorrhea alveolaris and chronic cryptic tonsillitis, chronic appendicitis, and peptic ulcer. When treatment appropriate to these conditions was instituted, the blood picture returned to normal, and the lead poisoning disappeared.

At this time a routine form of medication for those exposed to lead dust was initiated. This treatment consisted of the administration once a week—Monday—of 1 ounce of a saturated solution of magnesium sulfate, to which was added 15 grains of citric acid and sufficient tincture of eudbear to color the mixture; this was given to the men when they obtained their tools, thus insuring that practically all the men would receive medication before starting work. The results of this treatment, judged by the basophilic aggregation count and lack of serious complaints, were good, but were met with strenuous objection from the men.

Beginning in June, 1939, the foregoing medication was discontinued, and in its place each man was given two pieces of gum containing a total of 50 mg. of ascorbic acid. These were distributed about one-half hour after the noon lunch period. The men made no objection to taking the gum, and considered it a treat. Physical examinations and basophilic aggregation counts were continued as previously.

After a short period there was a noticeable decrease in muscular fatigue. This was evident by an increase in efficiency and a feeling of well-being at the end of the work period. The men seemed more cheerful and much less inclined to moroseness.

During the five months from June to December, 1939, the basophilic aggregation count showed a slow but progressive decline. At this time further laboratory studies were undertaken as follows: (a) urinalysis for lead, (b) basophilic aggregation count, and (c) a stipple cell count. These determinations were made each week for seven weeks, covering a period of thirty-five working days of eight hours each.

During this test period production was at its peak, humidity was high, and there was a slow circulation of air due to the low temperature of the outside air.

Urine was collected at different periods of the working day to obtain a fair average of lead excretion. A total of 1,996 analyses for lead were made, or an average of 6.5 analyses per man.

The results of the lead urinalysis are shown in Table I.

TABLE I

NO. OF MEN	PER CENT	AVERAGE OF URINARY LEAD EXCRETION PER LITER (γ)
99	32.6	39.5
96	31.6	61.5
48	15.8	86.2
24	7.9	110.4
14	4.6	134.5
10	3.3	160.9
5	1.6	189.6
3	0.9	219.3
1	0.3	265.0
2	0.6	405.0
1	0.3	541.0

Those below 100 γ per liter, 243 men, or 80.2 per cent, averaged 62.4 γ per liter.

Those above 100 γ per liter, 60 men, or 19.8 per cent, averaged 157 γ per liter.

The average over-all excretion of 303 men equaled 77 γ per liter.

In this series was one man who excreted an average of 541 γ per liter. Further questioning revealed that he had had acute lead intoxication several years previously. He had not worked with lead for eight years, and was at least two city blocks away from any lead; therefore, his exposure has been nil. Under the influence of vitamin C, we are evidently releasing the fixed lead from his bones and he is excreting it without showing any clinical symptoms of lead intoxication.

The workers who showed an average of more than 100 γ per liter of urine—60 men—were studied further. The urine and blood counts were continued at fortnightly intervals. At the end of April, 1940, the lead excreted in the urine has shown no decline, and the basophilic aggregation and stipple cell counts have remained within the normal range.

DISCUSSION

From the foregoing it is apparent that this study confirms the contention of Holmes³ that vitamin C (ascorbic acid) has a detoxifying action on lead in the human body. However, we cannot agree that the urinary lead excretion is decreased by the administration of vitamin C—since our findings show a continued high level of excretion over an observed period of five months in those workers continuously exposed to a high concentration of lead dust.

It is difficult to reconcile our findings with those of Shiels,⁴ and Blumberg and Scott⁵; i.e., that there are definite levels of concentrations for lead, both in urine and blood, above which levels, one finds lead poisoning. Judged by the criteria of blood cell counts, physical condition, and lack of symptoms usually associated with chronic lead absorption, the subjects of this study may be said to show no evidence of lead intoxication whatever. Fairhall⁶ has stated that a high urinary excretion of lead is not of itself evidence of lead intoxication, but rather of lead absorption only.

We have found no evidence that the storage of lead is promoted by vitamin C. Rather the reverse is true, as shown by the workman with the highest level of excretion in the group. As stated, this man has been previously exposed and has been treated for lead intoxication.

Further investigation in the deleading properties of vitamin C are being undertaken.

It seems possible that the effect of lead on the human economy may be only indirectly toxic, the absorption of lead producing an avitaminosis C. This is the condition of vague symptoms known as chronic lead poisoning, but is in reality chronic subclinical scurvy.

CONCLUSIONS

1. The routine administration of 50 mg. of ascorbic acid daily appears to protect workers exposed to lead dust against the usual effects of chronic lead absorption.

2. The rate of urinary excretion of lead in workers continually exposed to lead dust is not decreased by the routine daily administration of 50 mg. of ascorbic acid.

I wish to express my appreciation to Dr. Milton H. Kronenburg, Chief of Division, and K. M. Morse, Engineer, of the Illinois Industrial Hygiene Bureau, for the air-borne dust determinations; and to Doctors E. K. Nielsen and H. A. Cranston for the determinations of urinary lead.

CLINICAL CHEMISTRY

A COMPARISON OF THE HEMOGLOBIN RESPONSE TO VARYING DOSAGES OF IRON*

ADELAIDE P. BARER, PH.D., AND WILLIS M. FOWLER, M.D.
IOWA CITY, IOWA

ALTHOUGH the efficacy of simple iron salts in the treatment of iron deficiency hypochromic anemias has been adequately demonstrated, there is still a question as to the relative effectiveness of various sized dosages. The usually recommended doses are large and the present consensus is that a massive dose of iron is the advisable method of therapy. Balance studies have shown, however, that sufficient iron is retained from the administration of a smaller amount of the drug, so that adequate quantities are available for hemoglobin formation as well as for replenishment of the depleted reserves.^{1, 2} From those data it would seem that doses smaller than those usually recommended should produce a satisfactory increase in hemoglobin. The danger of large amounts of iron has been suggested by Elvehjem³ and others,⁴ and although we were unable to demonstrate that iron significantly affected the metabolism of calcium or phosphorus in the adult,⁵ the large doses may not be without danger. It was also shown in balance studies that large amounts of iron were retained by the body over long periods of time,¹ and although only one instance of a severe reaction to orally administered iron has been recorded,⁶ it does not seem wise to overburden the body with an excess such as must occur with the commonly employed doses when administered over a long period.

It has been demonstrated that large doses of iron produce a more rapid response in hemoglobin formation than do smaller amounts⁷⁻¹⁰ and that ferrous salts are more effective than ferric salts when compared on a basis of their metallic iron content.^{11, 12} Moore¹³ has shown that the serum iron absorption curves are higher following the ingestion of ferrous than of ferric salts. In order to compare the effectiveness of varying sized doses of iron and of various iron salts, we have administered these preparations to groups of patients with mild but comparable degrees of anemia under identical conditions.

From balance studies with iron and ammonium citrates the amount of iron excreted, retained, and utilized from a given dose was known,^{1, 2} so that this drug was selected for the first of the clinical trials. All subjects selected were healthy young adults, with no illness except the mild anemia which was detected on routine examination, and none was studied who had had a recent infection, hemorrhage, or other disability which might affect the blood hemoglobin. Hemoglobin determinations were done by the Newcomer method,¹⁴ hematocrits were

*From the Department of Internal Medicine State University of Iowa College of Medicine, Iowa City.

Received for publication, November 8, 1940.

determined by the Van Allen method,¹⁵ and erythrocyte counts were done on instruments certified by the United States Bureau of Standards. In the accompanying charts only the hemoglobin changes are recorded, although hematocrit readings and erythrocyte counts were done at the time of each hemoglobin determination.

Chart 1.—Iron and ammonium citrates.

To one group of 18 persons was given 0.5 Gm. (7½ grains) of iron and ammonium citrates per day. The average hemoglobin level for this group was 9.73 Gm. per 100 c.c. The average hemoglobin gain for the entire group in a period of six weeks is shown in Chart 1, and it will be noted that although there is an increase in hemoglobin, the gain is too slow to be considered a satisfactory response. During a subsequent six-week period 1.5 mg. of copper sulfate were added to the same dose of iron and the hemoglobin gain was no more rapid than without the additional copper.¹⁶ This amount of iron and ammonium citrates yields approximately 85 mg. of elemental iron per day, but from the results recorded here it is obvious that this amount of iron in the form of iron and ammonium citrates is inadequate to produce a satisfactory clinical response.

To a similar group of 15 persons, whose initial hemoglobin averaged 11.53 Gm., was given 1 Gm. (15 grains) of iron and ammonium citrates per day. This yields approximately 170 mg. of elemental iron per day, and the balance studies had shown that approximately 30 per cent of this, or 53 mg., was retained, and that 9.3 per cent, or 16 mg., was used immediately in hemoglobin formation, so that an abundance of metallic iron was being retained in the body.² With the administration of this amount of the drug there was a hemoglobin increase of such degree that the average gain at the end of twelve weeks was 1.82 Gm. per 100 c.c. of blood (Chart 1). Following this, as has been pointed out,¹⁷ there was a gradual reduction in the hemoglobin in spite of continued iron administration. It is well recognized that the rate of hemoglobin regeneration will depend on the degree of anemia as well as on the amount of iron administered. The anemia in this group of persons was mild and the gain of nearly 2 Gm. in the twelve-week period seems very satisfactory, although it is small in comparison with the results obtained in severe anemia.

A third group of 21 persons, with an average hemoglobin of 10.95 Gm., was given 3 Gm. (45 grains) of iron and ammonium citrates per day. This yields approximately 500 mg. of metallic iron per day; it has previously been shown that with this dosage 32.6 per cent of the iron was retained, but only 2 per cent of the amount administered was utilized immediately in hemoglobin formation in a group of 10 patients with an average hemoglobin level of 5.95 Gm.¹ This means that an average of 167.5 mg. of iron was being retained per day, 10.3 mg. was utilized in hemoglobin formation, and that 157.2 mg. was retained in addition to that used immediately in hemoglobin. With this dose of iron and ammonium citrates the average gain for the 21 patients was 1.78 Gm. at the peak of the response, a figure which is very similar to the response obtained with 1 Gm. of the same drug per day. The difference in the two groups lies in the fact that with 3 Gm. per day the peak of the hemoglobin production occurred in the eighth week instead of the twelfth week. The response was more rapid but no greater than with a smaller amount of iron (Chart 1). Following the peak in the hemoglobin response, there was a gradual regression during the following four weeks of observation in spite of continued iron administration.

Similar studies were carried out with small amounts of other simple iron salts for comparison with those obtained with iron and ammonium citrates. Reduced iron, 1 Gm. per day, was given to a group of 7 persons with an average hemoglobin of 11.36 Gm.; it produced a slightly greater increase in hemoglobin than did 1 Gm. of iron and ammonium citrates with the peak of the response in the tenth rather than in the twelfth week. Reduced iron is an insoluble preparation but one which is much higher in its metallic iron content than any other iron salt. As compared with 1 Gm. of iron and ammonium citrate, which contains approximately 170 mg. of metallic iron, 1 Gm. of reduced iron contains nearly 980 mg. of metallic iron so that the greater amount of iron compensates for its insolubility in producing the results shown in Chart 2.

Iron and sodium citrates, 1 Gm. per day, was administered to a group of 13 persons with an average hemoglobin level of 10.72 Gm. The results are shown in Chart 3. The response was somewhat less than with a similar dose of iron and ammonium citrates or reduced iron, but not significantly different.

Both clinical and experimental evidence points to the fact that ferrous salts are more effective than ferric salts when compared on the basis of their metallic iron content. This is substantiated by our results in which the administration of 0.36 Gm. (6 grains) of ferrous sulfate per day given to 11 persons with an average hemoglobin level of 10.58 Gm. produced a hemoglobin response comparable with those obtained with much larger doses of other iron salts (Chart 4). This amount of ferrous sulfate contains approximately 80 mg. of metallic iron as compared with 170 mg. in the smallest effective dose of iron and ammonium citrates and 980 mg. in reduced iron. It is comparable with the metallic iron content in 0.5 Gm. of iron and ammonium citrates which was shown to be ineffective.

It is interesting to note the similarity of the hemoglobin curve in every instance. As was pointed out in a previous communication, the hemoglobin increased to a peak; this was followed by a decline even though the same amount of iron was administered continuously. These persons were not fol-

Chart 2.—Reduced iron, 1 Gm. daily.

Chart 3.—Iron and sodium citrates, 1 Gm. daily.

Chart 4.—Ferrous sulfate, 0.36 Gm. daily.

lowed for as long a period as was true in the preceding study, but the hemoglobin curve had essentially the same contour for the shorter period and supports the idea of a stimulating or catalytic effect of iron^{10, 18} on hemoglobin formation.

It is useless to speculate on the minimal effective dose of an iron salt because this will vary so greatly in individual patients. Even the commonly employed doses need to be increased in certain cases to procure an adequate response. Hence the results reported here are not intended to be an argument for a wholesale reduction in the amount of iron administered per day to these patients. The renaissance in iron therapy has been due in part to the administration of larger amounts of this mineral, and these larger dosages are advisable in cases of severe anemia and when it is impossible to follow the patient by frequent hemoglobin determinations. It has been shown that 80 per cent of the patients respond satisfactorily to smaller doses¹² so that in the case of mild degrees of anemia or as a maintenance dose in idiopathic hypochromic anemia smaller amounts should be satisfactory for adequate therapy. The results are presented as a comparison of the effectiveness of varying amounts of iron in different iron salts in comparable cases.

SUMMARY AND CONCLUSION

When varying doses of iron and ammonium citrates were employed in the treatment of mild anemias, it was found that 0.5 Gm. per day was too small to be of value. The response to 1 Gm. of the drug per day was satisfactory, although the hemoglobin increase was less rapid than with 3 Gm. of the same preparation per day. Reduced iron, 1 Gm. per day, and iron and sodium citrates, 1 Gm. per day, gave practically the same response as did 1 Gm. of iron and ammonium citrates. Ferrous sulfate, 0.36 Gm. (6 grains) per day, was as effective as 1 Gm. of the other drugs, although the metallic iron content is much lower.

BLOOD FINDINGS IN LATE PREGNANCY*

J. W. MULL, PH.D., AND A. H. BILL, M.D.
CLEVELAND, OHIO

BLOOD findings on pregnant women may not logically be compared with those on normal nonpregnant women. Frequently the differences found between normal and complicated pregnancies are extremely important; as, for example, in toxemia, anemia, or following sulfamidamide therapy. For obstetric work, therefore, standards or ranges based on findings on normal pregnant women should be used.

In Table I we present such data for the carbon dioxide and oxygen contents of the blood, the oxygen capacity, the red blood cell count and volume, and the hemoglobin. The table includes the maximum and minimum findings and the averages from a series of 30 dispensary patients, whose histories and physical examinations indicated that they were normal pregnant women. From these results we have calculated by distribution formulas the range which will include individual findings on all normal pregnant women 95 per cent of the time. For comparison we have included the normal nonpregnant values for these same determinations, compiled from findings published in the literature and accepted by various texts.

The oxygen and carbon dioxide determinations were made, with a few unavoidable exceptions, in duplicate, in a manometric apparatus after the method of Van Slyke and Neill,¹ using oxalated venous blood, drawn free flowing from the arm under oil. Agreement between the duplicates was good, averaging less than 2 per cent difference. The red blood cell counts and red blood cell volumes were determined on the same samples, in the usual manner. Hemoglobin readings were made by the Sahli method, using a standard of 13.8 mg. per 100 c.c. as 100 per cent, and were also calculated from the oxygen capacity by formulas.[†] Fresh blood was used throughout and all work was completed in from three to five hours from the time the specimen was drawn.

*From the Laboratory of the Maternity Hospital and the Department of Obstetrics, Western Reserve University, School of Medicine, Cleveland.

Received for publication, November 15, 1940.

[†]Hemoglobin, in grams per 100 c.c. of blood, is found by subtracting the 0.5 volume per cent of physically dissolved oxygen from the oxygen capacity, and multiplying the result by the factor 0.746.

In view of the numerous factors which may affect the oxygen content of venous blood, of which Keys² found individual variation the greatest, our values for carbon dioxide and oxygen content are remarkably consistent, showing somewhat less variation than others have reported. Our range and average are a little lower than those Keys found with nonpregnant women, and also less than Eastman's³ 11 volumes per cent at delivery, or Smith's⁴ average of 12.1 volumes per cent for 10 women in labor, before anesthesia or delivery.

TABLE I

	NO. DETERMI- NATIONS	AVERAGE	RANGE OF ACTUAL DETER- MINATIONS	STANDARD DEVIATION	CALCULATED RANGE* (IN- CLUDES 95 PER CENT OF ALL NORMAL PREGNANT DETERMINA- TIONS)	NORMAL RANGE FOR NONPREG- NANT WOMEN TAKEN FROM THE LITERATURE
CO ₂ content in volume per cent	30	47.66	38.66-55.04	3.58	40.50-54.82	45-60
O ₂ content in volume per cent	30	6.90	2.80-12.13	2.18	2.55-11.25	11-17.6
O ₂ capacity in volume per cent	30	15.25	12.13-19.37	1.79	11.65-18.85	17-20
Erythrocytes per c.mm.	30	3.78	2.94- 4.79	0.53	2.71- 4.84	4.25- 5.00
Red blood cell volume in per cent	29	28.50	22.2-33.0	2.73	23.04-33.96	35-45
Hemoglobin by O ₂ ca- pacity	30	11.00	8.68-14.08	1.35	8.30-13.70	13.0-15.7
Gm. per 100 c.c.						
Hemoglobin by Sahli	24	11.00	8.42-12.97			13.8
Gm. per 100 c.c.						

*Two times the standard deviation added to and subtracted from the average gives the range which includes all individual determinations 950 times out of 1,000.

The oxygen capacity determination is more exact, since it is not affected by the factors which tend to vary the content, and is the same for both venous and arterial blood. Here again pregnancy causes a definite lowering from the generally accepted standards. For normal nonpregnant women Peters and Van Slyke⁵ give 17 to 21 volumes per cent oxygen capacity; Keys, 17 to 18; and Todd and Sanford,⁶ 18 to 24 for both men and women, men being conceded to average higher than women. Our average of 15.25 volumes per cent agrees well with Eastman's 15.4 at delivery, without anesthesia, and is but slightly lower than Smith's average of 16.8 for women in labor.

Oxygen capacity determinations are particularly practical following sulfanilamide therapy. This is illustrated by Table II, where we have presented a brief survey of the laboratory findings on 8 selected patients. Five of these, Nos. 1, 2, 3, 6, and 8, show a serious fall in oxygen capacity to a level below the lower limits, 11.65 volume per cent, of the normal pregnant range—3 by more than 2 volume per cent. In Case 2, even as low a concentration of sulfanilamide as 2.7 mg. per 100 c.c. of blood was sufficient to depress the oxygen capacity. Cases 4 and 7 show declines that were checked by blood transfusions and partial withdrawal of the drug. This decline in oxygen capacity only occasionally follows the use of the drug, but it is always a possibility that should never be

neglected. In the cases where it does occur, the oxygen-carrying power of the cells is apparently blocked, so that an oxygen tent is powerless to relieve the situation. This conclusion is supported by the fact that as the oxygen capacity falls different hemoglobin methods fail to agree, the colorimetric methods, either Sahli or alkaline hematin, invariably giving higher results. Further, there is no correlation between the blood count and the oxygen capacity. Withdrawal of the drug, supported by transfusions, restores the oxygen capacity and the agreement between the hemoglobin findings.

Another effect, illustrated in Cases 2, 4, 5, and 7, is the depression of the carbon dioxide content of the whole blood. This does not parallel the oxygen capacity fall, nor is it exactly proportional to the concentration of the drug in the blood, but it is relieved by withdrawal of the drug or by blood transfusions. No significance has so far been attached to it.

The per cent of oxygen saturation is varied not only by all the factors which affect the content, but also by those which affect the capacity. As is to be expected, our range is quite wide, and little significance can be attached to individual findings. The tendency to lower averages, however, is interesting. Smith reported 71.1 per cent for women in labor; Eastman, 71 per cent at delivery, with no anesthesia; and Keys, 62.8 per cent for nonpregnant women. We find an average of only 44.9 per cent for late pregnancy. Although the red blood cell count varies quite widely and is of less diagnostic value here than in other circumstances, it is consistently lower than that of nonpregnant normal women, averaging 3.77. The red blood cell volume, however, is quite consistent, averaging 28.5 per cent, as opposed to the nonpregnant 40 per cent. The hemoglobin derived from the oxygen capacity naturally parallels those values, and shows little variation. The Sahli findings likewise are very consistent and agree remarkably with the other hemoglobin values, averaging the same. While the findings on a given individual do not always agree, it is worthy of note that no Sahli readings fall outside the calculated range established by the oxygen capacity method for hemoglobin.

There is less interrelation between these different blood findings than might be anticipated. The oxygen and carbon dioxide contents might seem to be inversely proportional, but upon applying Pearson's correlation formulas we find the relation just fails of significance. Neither is there a direct relation between the red blood cell count and red blood cell volume, probably due to variation in the size of the red blood cells, even when applying Pearson's less exact rank formulas, which take into account only the order of magnitude instead of exact values. The oxygen capacity and red blood cell volume did show a bare significance, but in view of the short series reported, this can only be noted as a tendency which might be confirmed in a longer series.

Apparently neither age nor the number of children affects the blood findings. Seven individuals reported were over 25, two were 40, yet none show any significant variation from the general average. Similarly, 11 of the 30 had 2 or more children, one 5, one 6, and one 9; yet these, too, agree with the general averages.

SUMMARY

Tables of blood findings, including the calculated ranges for normal cases of late pregnancy, are presented.

The practical value of laboratory work for patients on sulfanilamide or allied drug therapy is illustrated with a few selected cases, showing a serious fall in oxygen capacity unrelated to the red blood cell count.

Lack of correlation is demonstrated between the widely varying red blood cell counts and the more uniform red blood cell volumes, while a tendency toward correlation is indicated between the oxygen capacity and the red blood cell volume.

A rough parallel is shown between the colorimetric Sahli hemoglobin readings and those calculated from the oxygen capacity, and thus between the Sahli readings and the oxygen capacity.

CORRELATED HEMATOLOGIC, PHYSICAL, AND CHEMICAL STUDIES OF THE BLOOD AND STROMA IN POLYCYTHEMIA AND BEEF EMBRYO*

BETTY NIMS ERICKSON, M.S., OLIVE HOFFMAN, PH.D., ELIOT F. BEACH, PH.D.,
HAROLD H. WILLIAMS, PH.D., AND ICIE G. MACY, PH.D., DETROIT, MICH.

INVESTIGATIONS of the blood in hemolytic¹ and pernicious anemias² have shown marked alterations in erythrocyte composition, and chemical study of posthemolytic residue, or "stroma," prepared from the blood of dogs with experimental disulphide anemia has proved that abnormalities in the chemical structure of the red blood cell may be induced by anemia.³ Human polycythemia offers a striking hematologic contrast to the anemias; furthermore, it provides an opportunity to secure sufficient human blood for complete hematologic, physical, and chemical investigations, together with the simultaneous preparation and study of the erythrocyte stroma.

Our present objective has been to make a coordinated and as thorough investigation of the blood in polycythemia as possible. The detailed study of a few

*From the Research Laboratory, Children's Fund of Michigan, Detroit.

A preliminary report of this study was presented before the annual meeting of the American Society of Biological Chemists, Toronto, Canada, April, 1939.

Received for publication, November 8, 1940.

specific cases has been chosen rather than less exhaustive observations upon a larger number of patients. In order to interrelate the hematologic, physical, and chemical characteristics of the blood with that of the stroma or fixed framework of the erythrocyte, a relatively large quantity of blood, from the standpoint of the human subject, must be obtained, despite the use of microchemical methods of analysis. From 30 to 50 ml. of blood are required for all the hematologic, physical, and chemical measurements. An additional quantity (250 to 500 ml.) of blood must be secured for the stroma preparation.* From 5 to 10 Gm. of erythrocyte posthemolytic residue or stroma are required for lipid and amino acid analyses.

The patients of this study have been under clinical observation and treatment for a number of years, and inasmuch as the withdrawal of blood at periodic intervals was the procedure used to control the polycythemia, it offered the first opportunity to make this type of investigation with human beings.

EXPERIMENTAL

Two established cases of primary polycythemia vera and one of cardiac origin were studied. Subject J. S.† (male, aged 49 years) had been under observation for over ten years. Treatment with phenylhydrazine and x-ray had been used, but not in the three years prior to the time at which these studies were made. Subject P. H.‡ (male, aged 31 years) exhibited a mild polycythemia vera, with a red blood cell count never above 7.5 million per cubic millimeter. Subject A. D.‡ (male, aged 31 years) suffered from a congenital heart deficiency and was reported to have been cyanotic since infancy. All three patients were being treated by periodic venesection during the time these studies were made.

Samples of blood for chemical analysis and stroma preparation were removed by venepuncture. Determinations of red blood cell count, hemoglobin, hematocrit, diameter, specific gravity, and water content were made; from these, corpuscular volume, weight, thickness, and hemoglobin and water content were calculated. The chemical data included mineral analyses (sodium, potassium, chloride, calcium, and phosphorus) of the serum and red blood cells; the lipid distribution (total, free, and esterified cholesterol, total phospholipid, lecithin, cephalin, sphingomyelin, cerebrosides, and neutral fat) of the plasma and erythrocytes; and the amino acid and lipid partition of the stroma prepared from the erythrocytes. The hematologic and chemical methods have been outlined in previous studies from this laboratory,⁴⁻⁶ as has the procedure developed for the preparation of the posthemolytic residue.⁷

*Preparation of stroma involves separation of the fixed framework of the erythrocyte. The erythrocytes are separated by centrifugation and washed then hemolyzed in physiologic saline. The washed erythrocytes are run through resuspended in a buffer (pH 5.0 to 5.5). The material is then again placed in 20 volumes of buffer and run through a refrigerator. This suspension is ground in a ball mill in a vacuum oven and powdered.⁷

†We wish to thank Dr. E. A. Sharp of Parke, Davis & Co. and the staff of the anemia clinic of Harper Hospital for their cooperation in making accessible these cases for study, and for their assistance in the collection of the blood samples.

‡We appreciate the courtesy of Dr. Warren B. Cooksey and Dr. Hugo A. Freund in arranging and assisting with the studies on patient P. H.

RESULTS AND DISCUSSION

The hematologic and physical characteristics of the erythrocytes are given in Table I. The average red blood cell of the mild polycythemia vera (P.H.) is of normal size, shape, and weight, in agreement with general literature reports; the volume and weight in the more severe case (J.S.) show some decrease. Both cases demonstrate a decreased quota of hemoglobin per cell. In contrast, the erythrocyte of the cardiac polycythemia (A.D.) exhibits a full quota of hemoglobin and increased volume and weight owing in part to elevated mineral and lipid contents, but chiefly to an augmented water content. Values indicative of the weight of the nonhemoglobin protein of the cell are low for polycythemia vera (1.1 and 2.1 Gm. $\times 10^{-12}$) but normal in the cardiac case (3.3 Gm. $\times 10^{-12}$). Comparable, but slightly lower values, are obtained from the difference between the total nitrogen of the cryoscopically dried cell and that accounted for by the hemoglobin and lipid.

TABLE I

HEMATOLOGIC AND PHYSICAL CHARACTERISTICS OF ERYTHROCYTES IN POLYCYTHEMIA

	NORMAL	POLYCYTHEMIA		
		VERA		CARDIAC
		J. S.	P. H.	A. D.
Hemoglobin (Gm./100 c.c.)	15.4	17.5	15.6	24.3

Undetermined weight ($\times 10^{-12}$ Gm.)	3.0	2.1	1.1	3.3
Nonhemoglobin protein/lipid ratio	4.9	--	2.3	2.0

The mineral analyses of the serum and erythrocytes are given in Table II. The values for serum water, protein, sodium, potassium, chloride, calcium, and phosphorus are within normal limits. Values for the mineral and lipid composition of the erythrocytes are given in terms of average corpuscular concentration, rather than on the basis of a unit weight of cells, in order to compare the composition of the individual cell in the various conditions.^{1,4} Only in cardiac polycythemia were abnormalities displayed in the erythrocyte content of minerals; increases were found in sodium, chloride, and water. Calculation on the basis of milliequivalents per liter of cell water further demonstrates the elevated chloride and sodium values, and, in addition, a compensatory decrease in potassium.

Data on the lipid distributions of the plasma, cells, and stroma are presented in Table III. A reduced free cholesterol in the plasma of polycythemia vera was a consistent finding. An increased plasma phospholipid with a significantly higher proportion present as cephalin was observed in the patient with cardiac polycythemia. Although Boyd has reported no disturbance in the concentration of plasma lipids in polycythemia,⁸ inspection of his data reveals trends similar

to those noted above; i.e., a reduced free cholesterol in polycythemia vera and an elevated phospholipid in secondary polycythemia.

The data demonstrate that the increase in total corpuseular lipid in polycythemia vera is due mainly to an elevated total phospholipid, which is reflected in the cephalin and sphingomyelin fractions. In the patient with cardiac disorder the marked augmentation of corpuseular lipid is accompanied by corresponding increases in free cholesterol and neutral fat as well as total phospholipid. It seems significant, however, that the major increase occurs in the phospholipid and is reflected in all three fractions, cephalin, sphingomyelin, and lecithin.

TABLE II
MINERALS OF SERUM AND ERYTHROCYTES IN POLYCYTHEMIA*

	NORMAL†	POLYCYTHEMIA		
		VERA		CARDIAC
		J. S.	P. H.	A. D.
Plasma protein (Gm./100 c.c.)	7.1	7.2	6.9	8.1
Serum:				
Sodium (meq./liter)	140	140	143	143
Potassium (meq./liter)	4	7	4	7
Chloride (meq./liter)	103	97	101	103
Water (Gm./liter)	944	932	935	936
Erythrocyte:

Chloride (meq $\times 10^{-13}$ /cell)	45	45	51	70
Water (Gm. $\times 10^{-12}$ /cell)	63	63	69	75
Serum:				
Sodium (meq./liter of water)	148	150	153	153
Potassium (meq./liter of water)	4	8	4	7
Chloride (meq./liter of water)	100	104	108	110
Erythrocyte:				
Sodium (meq./liter of water)	25	31	27	54
Potassium (meq./liter of water)	144	141	179	117
Chloride (meq./liter of water)	72	66	69	86

*Values for calcium, inorganic, and acid-soluble phosphorus, in serum and erythrocytes, were normal.

†Values from previous studies^{2,4}

The increased phospholipid, particularly the cephalin and sphingomyelin fractions, is in striking contrast to the characteristic changes of the erythrocyte composition in severe anemia;^{1,2} it is similar, however, to the chemical alterations induced in the red blood cells by liver therapy in pernicious anemia during the period of active reticulocyte response.^{2,9} There seems to be no evidence, therefore, of an accumulation of old cells exhibiting fatty degeneration; rather, the mass presence of young cell forms and active bone marrow stimulation.* These findings are in agreement with hematologic observations of the presence of immature red blood cell forms in the circulation^{10,11} and the histologic evidence of increased erythroblastic activity of the bone marrow in polycythemia.^{12,13}

The augmented lipid content of the erythrocyte may be indicative of a greater amount of fixed lipid structure, inasmuch as experimental data have

*An increased span for beginning and complete hemolysis by hypotonic sodium chloride solutions gave evidence of the presence of cells of varied ages, particularly immature forms. The periodic venesection may have had some effect upon bone marrow activity and the type of erythrocytes released into circulation.

shown that practically all of the lipid in the intact erythrocyte is combined with the stroma.¹⁴ The posthemolytic residue prepared from the erythrocytes in polycythemia exhibited an elevation of total lipid, chiefly cholesterol (Table III). An augmented phospholipid content was found in the preparations from P. H. and A. D. and was reflected in the sphingomyelin and cephalin fractions, respectively. The differences between cells and stroma in the phospholipid partition indicate that a portion of that present in the whole cell is not combined with the stroma. These lipid anomalies are diametrically different from those found in the red blood cell stroma of dogs subjected to experimental N-propyl disulfide anemia, in which reductions of total lipid, phospholipid, and cholesterol were observed.³

The lipid distribution of the posthemolytic residue of embryonic beef erythrocytes (Fig. 6) has been included (Table III) in view of suggestions that polycythemia vera may be analogous to fetal polycythemia.¹⁵ No similarities between the lipid abnormalities of the embryonic beef and polycythemia vera erythrocytes are evident. In fact, the embryonic preparations, in comparison with stroma from erythrocytes of adult beef, exhibit lower total lipid, free cholesterol, and phospholipid, differences which are suggestive of the anemias, and recall the hematologic similarities of fetal and pernicious anemia erythrocytes.¹⁵

[†]Values from previous studies.⁶

[‡]Average of 4 preparations with average deviation from the mean.

[§]Average of 5 preparations with average deviation from the mean

The protein fraction of the posthemolytic residue has been analyzed for six amino acids: arginine, histidine, lysine, cysteine, tyrosine, and tryptophane. Since these amino acids do not have uniform molecular weights or nitrogen contents, the analyses are expressed in terms of millimols per 100 Gm. of protein in Table IV. In polycythemia vera less histidine was found than is present in normal stroma; in the severe case (J. S.) the decreased histidine was accompanied by an increase in cysteine content. The stroma protein from the cardiac polycythemia erythrocytes contained more cysteine but less arginine and lysine than normal.

If 35,000 is taken arbitrarily as the molecular weight of the stroma protein, then a deviation from the normal of 2.86 millimols of an amino acid per 100 Gm. of protein represents a variation of 1 Gm. mol of that amino acid per 35,000 Gm. of protein, and may be considered a significant difference. By this criterion only

cysteine differs significantly (one-half to 1 mol) in the preparations of J.S., while histidine is lowered by 1 to 2 Gm. mols per 35,000 Gm. protein in the stroma of P.H. In the cardiac case, both arginine and lysine are diminished significantly (2 mols).

TABLE V
SIGNIFICANCE OF DIFFERENCES* IN AMINO ACID ANALYSIS
(MILLIMOLS PER 100 GM. OF PROTEIN)

	POLYCYTHEMIA			EMBRYONIC BEEF
	VERA		CARDIAC	
	J. S.	P. H.	A. D.	
Arginine	-0.9	-0.1	-8.0	-0.3
Histidine	-1.8	-1.8	0	-0.7
Lysine	-1.2	+0.8	-5.0	+7.0
Cysteine	+2.4	+0.5	+1.3	+3.3
Tyrosine	+0.4	+0.7	-	+0.9
Tryptophane	0	-0.3	-	-0.2

*A variation from the normal of 2.86 millimols per 100 Gm. of protein is equivalent to 1 mol of an amino acid per 35,000 Gm. of protein (the assumed molecular weight), and therefore, a difference of this magnitude or larger may be considered significant.

The amino acid analyses of the embryonic beef erythrocyte residues* exhibit significant differences in comparison with preparations from adult beef erythrocytes, but differences which are not similar to those displayed in polycythemia. Outstanding is the increase of the lysine fraction by 2 mols, and the cysteine by 1 mol.

This evidence of abnormalities in the amino acid composition of stroma in polycythemia is unique, in view of previous studies which have shown that posthemolytic residue preparations from the erythrocytes of 5 mammalian species were practically identical in amino acid composition.⁶ Furthermore, no alterations were found in the amino acid composition of red blood cell stroma of dogs with experimental disulfide anemia.³

SUMMARY

Correlated hematologic, physical, and chemical investigations of the blood plasma and erythrocytes have been made in two cases of polycythemia vera and one of secondary polycythemia. These studies have been accompanied by detailed lipid and amino acid analyses of the erythrocyte posthemolytic residue or stroma. Analyses on the stroma of embryonic beef erythrocytes are included for comparison.

The data indicate significant alterations not only in the composition of the intact erythrocytes but also in the lipid and amino acid constitution of their so-called fixed structure or stroma. Increased corpuscular total lipid and phospholipid, accompanied by corresponding increases of cephalin and sphingomyelin were the salient characteristics. The posthemolytic residues prepared from the erythrocytes exhibited an elevation of total lipid and cholesterol. The data indicate, however, that not all the augmented phospholipid evident in the cell in polycythemia is bound with the stroma.

*These differences in composition of the erythrocyte residue of embryo bloods from that of the normal adult have suggested a study which is now in progress: the pattern of the chemical composition of tissues during growth.

No similarities were evident between the stroma from the erythrocytes of beef embryos and polycythemia in their lipid anomalies.

Significant, but dissimilar, differences were found in the amino acid composition of the erythrocyte stroma protein from polycythemia vera, cardiac polycythemia, and embryonic beef preparations.

The cardiac polycythemia exhibited more marked and extensive changes in the mineral and lipid composition of the erythrocyte as well as the lipid and amino acid make-up of the posthemolytic residue.

These data in polycythemia add further evidence to those in the anemias that the stage of maturation of the erythrocyte may be reflected closely in its lipid composition and that of the posthemolytic residue.

THE CHEMISTRY OF INFECTIOUS DISEASES*

I. POLAROGRAPHIC STUDY OF BLOOD SERA IN EXPERIMENTAL PNEUMONIA IN DOGS

M. L. CROSSLEY, PH.D., R. H. KIENLE, PH.D., BRUNO VASSEL, PH.D.,
AND G. L. CHRISTOPHER, PH.D., STAMFORD, CONN.

BRDICKA¹ reported that carcinomatous serum gave a typical polarographic curve, differing from that given by normal serum, by which early cases of malignant growth could be detected. Waldschmidt-Leitz,² in a study of over 500 cases, confirmed this observation. A check on the polarographic findings by clinical methods revealed that less than 10 per cent of the polarographic diagnoses were incorrect. Of these the wrong positive diagnoses were always of a deep-seated inflammatory nature, which prompted us to investigate the influence of severe pneumoecal inflammations on the normal polarographic curve of serum.

EXPERIMENTAL

All dogs were infected† by the method of Terrell, Robertson, and Coggeshall³ by the direct introduction of type I pneumococcus culture‡ into one lobe of the lung after the dog's body temperature had been lowered 3° to 4° F. by the subcutaneous injection into the groin of a saline solution of 6 mg. of morphine sulfate per kilogram of body weight.

After infection periodic samples of 5 to 8 c.c. of blood from either the cephalic or the external jugular veins were taken every three to four hours for the first thirty hours after infection, later twice daily, and then once until the dog had recovered or died. The sera were obtained in the usual way from the clotted and centrifuged blood.

Plenty of water was available to the animals at all times. A sufficient amount of our usual dog diet (horse meat and Purina Dog Chow) was given once a day. During the first and second days after infection the dogs often did not eat food.

A Heyrovsky self-recording polarograph was used throughout this work. The buffer solution for the serum analyses was similar to the one recommended by Brdicka.¹ It was prepared as follows:

*From the Research Laboratories of the American Cyanamid Co., Stamford, Conn., and the Calco Chemical Division, Bound Brook, N. J.

Received for publication, February 13, 1941.

A report of this work was presented at the One Hundredth Meeting of the American Chemical Society at Detroit, Mich., September 9 to 13, 1940.

†We gratefully acknowledge the invaluable help and the unstinted cooperation we received in this study from Dr. W. Harry Feinstone of this laboratory. Dr. Feinstone, while actively studying related phases of pneumococcal infection in dogs, kindly took over the culturing of the pneumococci and the actual infection of the dogs, and followed the progress of the disease systematically with x-ray photographs.

‡Furnished through the courtesy of Dr. O. H. Robertson, of the University of Chicago.

10 c.c. of a cobaltic hexammino-chloride solution (0.2776 Gm. in 100 c.c. H ₂ O; decomposes within a few hours)
5 c.c. 1 N ammonium chloride
15 c.c. 1 N ammonium hydroxide
70 c.c. water
100 c.c. solution

In the analyses of whole serum, 0.45 c.c. of water was added to 0.3 c.c. of serum, and 0.1 c.c. of this diluted serum solution was electrolyzed in the presence of 10 c.c. of the cobalt buffer. The current-voltage curves were recorded in all cases from -0.9 to -1.7 volts. The sensitivity of the instrument was set at $\frac{1}{200}$, with an accumulator voltage of 4.0 volts. The dropping rate of the mercury electrode was 2.8 seconds per drop into the buffer solution at zero potential.

A variation from this procedure, also recommended by Brdicka¹ and referred to in this paper as "peptone fraction," consisted in the denaturation of 0.4 c.c. of serum with 1 c.c. of 1 N potassium hydroxide for exactly forty-five minutes, then precipitation of the macropoteins with 1 c.c. of 20 per cent sulfosalicylic acid and filtration after ten minutes' standing. One-half cubic centimeter of the filtrate was added to 5 c.c. of the cobalt buffer for electrolysis. The current-voltage curves were recorded as described under whole serum, except that the sensitivity was set at $\frac{1}{100}$.

The solid content of serum was determined by drying exactly 1 c.c. of serum in a weighing flask to constant weight in a vacuum desiccator over phosphorus pentoxide at room temperature.

TABLE I

AVERAGE, MAXIMUM, AND MINIMUM VALUES OF THE DIFFERENCES IN POLAROGRAPHIC WAVE HEIGHT BETWEEN -1.65 AND -1.06 VOLTS OF FIVE DOGS INFECTED WITH TYPE I PNEUMOCOCCUS

Differences between -1.65 and -1.06 volts in centimeters.

DOG NO.	NO. OF DETERMINATIONS	NORMAL DOGS			INFECTED DOGS
		AVERAGE	MAXIMUM	MINIMUM	MINIMUM

II	10	2.13	2.29	1.96	1.86
III	16	1.99	2.44	1.89	1.68
VI	18	2.15	2.35	1.97	1.69
VIII	3	2.04	2.14	1.96	1.68

RESULTS AND DISCUSSION

A polarographic wave of the whole serum of Dog VI prior to infection is recorded in Fig. 1, curve I, while Fig. 1, curve II, is the corresponding curve of the serum at the height of infection. It can be seen from the two figures that the minimum at -1.65 volts in the case of the normal serum is higher in relation to the flat part of the curve at -1.06 volts than the corresponding minimum of the infected serum. We selected, as a base line, the value at -1.06 volts, even though it is on a slope, since it represents the maximum of the current-voltage curve of the cobalt-buffer solution in the absence of proteins, and because it is very easily reproducible for a given serum. If this difference is plotted against

Fig. 1.—Polarograms of whole dog sera before (curve I) and after (curve II) infection with type I pneumococcus.

Fig. 2.—Polarographic wave height of whole dog sera after infection with type I pneumococcus

time, i.e., hours after infection, a curve such as shown in Fig. 2 for Dog VI is obtained. During the first thirty to fifty hours after infection, a sharp drop in the wave height occurred in all the five infected dogs studied. The return to normal values is then very rapid. However, the decrease is not uniform and loses much of its value due to the fluctuations in the wave height of the normal sera of the same dog, as shown in Table I, which summarizes the distances in

Fig 3—Polarograms of the filtrates of potassium hydroxide denatured, sulfosalicylic acid precipitated dog sera before (curve I) and after (curve II) infection with type I pneumococcus

Fig. 4.—Changes in polarographic wave height (curve I) and nitrogen content (curve II) of the peptone fraction of sera (i.e., filtrate from potassium hydroxide denaturation and sulfosalicylic acid precipitation) and body temperatures (curve III) of the same dog with time after infection with type I pneumococcus

centimeters between -1.65 volts and -1.05 volts of the five infected dogs at the height of the illness, as well as the averages, maximum and minimum values of the corresponding normal blood samples.

The decrease in wave height, nevertheless, is real, reproducible, and undoubtedly represents some change in the serum with infection. Probably it is due to a decrease in proteic sulfhydryl and disulfide groups, i.e., a decrease in cystine (and cysteine) in peptide linkage, for we confirmed Brdicka's observa-

tion⁴ that proteins with little or no cystine sulfur (protamine and gelatin) as well as free cystine and cysteine, give no typical protein double wave in the trivalent cobalt buffer, while glutathione produces slight, and cystine-rich proteins a pronounced, double wave. The addition of free cystine either to serum or to crystalline serum albumin, buffered with trivalent cobalt, also does not increase the wave height from that given by the same amount of serum or albumin without the cystine.

While the polarograms of whole sera decrease in wave height with infection, probably indicating concentration changes, the current-voltage curves of the peptone fraction not only increase in wave height, but also undergo a pronounced alteration in the slope of the curves. This is clearly demonstrated in Fig. 3, curves I and II, which represent enlarged reproductions of the polarograms of normal and infected peptone fractions, respectively, of blood sera of Dog VI. It should be observed that the most pronounced changes in appearance of the curves occur at -1.65 volts. With an increase in infection the pronounced minimum of the double wave of normal serum gradually flattens out until, during severe infections, the curve at -1.40 volts becomes almost a straight line sloping upward. As the infection recedes, the height of the wave decreases until, upon complete recovery, the typical curve of a normal serum is obtained. If the difference in the peptone wave height between -1.65 volts and -1.18 volts is plotted against time after infection, a curve such as shown in Fig. 4, curve I (Dog VI), is obtained. The reason for choosing -1.18 volts as a base line, even though it falls on a slope, is that the value is constant in all normal dogs and changes very little during the entire period of infection. The peptone-fraction graphs of seven infected dogs show the same general tendency as the one represented in Fig. 4, curve I, for Dog VI, the only differences being that the absolute values of the peaks in the wave height, as well as the exact time after infection at which the peaks occur, vary with each dog. After recovery from the illness all seven dog curves return to their normal values, which lie between 0.85 and 1.25 cm. wave height difference (1.65-1.18 volts), while the peaks reached by the seven infected dogs, together with the respective times after infection at which they occurred (in parenthesis), are: 2.61 cm. (144 hours), 2.20 cm. (127 hours), 2.14 cm. (92 hours), 2.13 cm. (93 hours), 2.11 cm. (144 hours), 2.00 cm. (46 hours), and 1.61 cm. (102 hours). The greatly increased wave height of the peak in the first-mentioned animal is very interesting, since the dog died during the night after this particular blood sample had been taken. Profound alterations in the serum of this dog must have occurred, and speculations as to the relationship between the changes in the serum, which are measurable by the polarograph, and to the cause of death, are very attractive and worthy of a continued study of this problem.

The observed decrease in the galvanometer deflection when whole serum is studied amounts to 10 to 15 per cent of the normal value. This change can undoubtedly be attributed to changes in the solid content of the serum, for a dilution of the serum of from 8 to 13 per cent is found in the case of two of the dogs studied. At least part of this decrease in solid content must be

attributed to nitrogenous constituents, for the total nitrogen values drop from 1,000-1,100 mg. per cent to 800-950 mg. per cent.

The nitrogen values of the peptone fraction, on the other hand, increase during infection by about 100 per cent and parallel closely, in time and percentage, the changes in the polarographic wave height. This can be seen in Fig. 4, curves I and II, where for better comparison the polarographic peptone wave height, as well as the milligrams of peptone nitrogen of Dog VI, are plotted against time after infection. Curve III in Fig. 4 represents degrees of fever during the infection. It is felt that while the nitrogen values agree fairly well with the changes in polarographic wave height, the same corollary with fever does not hold nearly so well. At least fever is not the direct cause of the observed polarographic changes, since the onset, rise, and fall in the fever curves of all seven dogs occur much sooner and more rapidly than the polarographic changes.

SUMMARY

Polarographic studies of normal and of type I pneumococci-infected dog sera are presented.

The wave height of the current-voltage curves of whole sera decrease during infection and return to normal with recovery. It is felt that these changes may be associated with corresponding shifts in the protein-cystine content of the sera.

The polarograms of the peptone fraction of dog sera, i.e., that fraction which, after alkali denaturation, is not precipitated by sulfosalicylic acid, increase in wave height as well as change their shape during infection. Recovery is associated with a return to normal values. With the increase in wave height during illness, a corresponding increase in nitrogen values occurs, while the fever curves do not directly parallel the polarographic changes.

We are greatly indebted to Mr. O. E. Sundberg, of the Calco Chemical Division of the American Cyanamid Co., for his cooperation in determining all the serum nitrogen values reported in this paper by the micro-Kjeldahl method.

STUDIES IN DYSTROPHIA MYOTONICA*

VI. RESULTS OF GLUCOSE TOLERANCE TESTS

MARION REINHARDT RYMER, PH.D., AND ABE RAVIN, M.D.
DENVER, COLO.

THE hypothesis has been advanced that the muscular changes in dystrophia myotonica are of endocrine origin; certainly many of the later symptoms of the disease suggest endocrine dysfunction. Defects of carbohydrate metabolism⁶ and storage⁸⁻¹⁰ have also been suggested as the cause of the weakness and atrophy of the muscles. A study of the glucose tolerance in these patients might furnish some information about the state of the endocrine system and carbohydrate metabolism; differences in capillary and venous blood glucose during glucose tolerance tests might give some clue to the utilization of glucose by the tissues; a variation in response to different doses of glucose might disclose borderline pathologic change. Accordingly, observations were made on both capillary and venous blood following the ingestion by each patient of two different doses of glucose.

Previous reports on the subject of fasting blood sugars and sugar tolerance tests in the muscular dystrophies and other severe muscular disorders are meager and often conflicting. In cases with *dystrophia myotonica* Sehranke and Full¹ reported no glycosuria following 150 Gm. of glucose (1 case); Brock and Kay,² a normal fasting glycemia and no glycosuria following 200 Gm. of glucose (1 case); Keschner and Finesilver,³ a prolonged hyperglycemia following breakfast (1 case); d'Antona,⁴ a fasting hypoglycemia (2 cases); a fasting hyperglycemia (1 case); a normal, a low prolonged, and a high prolonged glucose tolerance test (1 case each); Morgulis and Spencer,⁵ consistent zigzag tolerance curves with glycosuria in some instances. In cases of *muscular dystrophy*† Janney, Goodheart, and Isaacson⁶ found a lasting hypoglycemia (9 cases); McCrudden and Sargent,⁷ fasting hypoglycemia (3 cases, progressive type); Hughes and Shrivastava,⁸ hyperglycemia following 50 Gm. of glucose (2 cases, Erb's type); Braestrup,⁹ normal fasting glucose (3 cases); prolonged hyperglycemia and normal capillary-venous blood sugar differences following 1 Gm. of glucose per kilogram body weight (2 cases); normal glycemia and no capillary-venous differences (1 case). In cases with *myasthenia gravis* McCrudden and Sargent⁷ reported a slight fasting hypoglycemia (2 cases); Williams and Dyke,¹⁰ a normal tolerance test following 50 Gm. of glucose but a prolonged

*From the Departments of Medicine and Biochemistry, University of Colorado School of Medicine and Hospitals, Denver.

Received for publication, May 6, 1940.

†In early, and even in more recent reports, dystrophia myotonica has not always been distinguished from other muscular dystrophies. From the descriptions given by Janney, Goodheart, and Isaacson, it appears quite likely that at least two of their patients may have had dystrophia myotonica. Likewise, the patient described by Brock and Kay undoubtedly had dystrophia myotonica rather than myotonia congenita.

hyperglycemia following 100 Gm. (3 cases); Adams, Power, and Boothby,¹¹ normal glycemia (5 cases). In one case with *progressive muscular atrophy* Braestrup⁹ found no capillary-venous differences during the glucose tolerance test.

METHOD

The 7 patients used in this study have been described in a previous article of this series.¹² The controls, in the same age groups as those with dystrophia myotonica, were 5 clinic patients and one of us (M. R.), carefully examined and found normal. None of the persons used in these studies was undergoing any kind of treatment at the time of the test or for a week previously.

The experiments were performed in the morning on persons who had received no food since the preceding evening. Blood was withdrawn from the brachial vein through a small needle into a syringe and immediately transferred from the tip of the syringe to two Folin¹³ blood pipettes calibrated "to contain"; the blood was discharged into two tubes of acid cadmium solution, and in the pipettes were thoroughly rinsed by drawing the solution up into them several times. Duplicate samples were then taken from a finger tip* directly into two Folin blood pipettes and discharged into the acid cadmium solution. An average of 3.4 minutes (range two to seven minutes) elapsed between the completion of the venous sampling and the completion of the capillary sampling. After a sample of urine had been collected, the patient received the measured amount of glucose dissolved in 250 c.c. of water flavored with lemon juice. Blood and urine samples were again taken at one-half, one, two, and three hours after the ingestion of glucose. All patients spent the time during the test in reading, resting, and walking about the halls. The test was performed twice within two weeks on each person, once with 50 Gm. of glucose and once with 100 Gm., though not necessarily in this order. Blood sugar values were determined by the Miller and Van Slyke¹⁴ method. All solutions were repeatedly rechecked or standardized as required; all volumetric apparatus was carefully calibrated at the beginning of the work. Duplicate analyses were performed in all the experiments and gave an average difference of 2.6 mg. per cent, with a range of 0 to 9 mg. per cent.

RESULTS

In all cases the fasting level of the blood was normal and no differences were evident between the controls and the patients in this respect. No glycosuria occurred in any of the tests. To conserve space, the individual data on the controls, which gave normal glucose tolerance curves in all respects at both levels of glucose, have merely been summarized in Table I. Since the rise in blood sugar is greater in the capillary blood than in the venous blood, two tolerance curves, one for the venous and one for the capillary blood, were obtained for each test, but the interpretation of the results of these tests is similar.

Results With 50 Gm. of Glucose.—The results for patients with 50 Gm. of glucose are very similar to those for the controls. The fasting values rise sharply

*Foster¹⁵ demonstrated that in studies on blood glucose, cutaneous blood could be substituted for pure arterial blood.

*Figures in roman type represent values obtained with 50 Gm. of glucose; those in italics with 100 Gm. of glucose. Blood values as milligrams per cent at minutes noted.

from normal to a peak, which is usually reached at thirty minutes but may be delayed until sixty minutes; the values then decline at the end of the third hour to below the fasting level, with one exception (J. B.). The peaks of the curves in both venous and capillary blood average about 15 mg. per cent less than the corresponding controls, but the variations from individual to individual in both patients and controls are so great that these differences scarcely can be considered significant. The peaks for the venous curves appear somewhat low, with a range of 108.0 to 138.3 and an average of 117.4 mg. per cent. However, since this represents an average increase of approximately 39 per cent over the fasting level, and since the smallest percentage increase is 26.7, these curves can be considered normal.

Comparison of the Results Obtained Following 100 Gm. of Glucose With Those Obtained Following 50 Gm.—MacLean and de Wesselow,¹⁶ and Williams and Dyke,¹⁰ found that in normal persons increasing the dose of sugar over about 25 to 50 Gm. gave no increase in the peak of the resulting hyperglycemia but tended to prolong the period during which the blood sugar was raised. Gray¹⁷ noted that the variations in glucose tolerance curves were as great from individual to individual as from different sized doses. Strouse¹⁸ reported that blood sugar values obtained in normal persons by giving 100 or 150 Gm. of glucose could be considerably increased in the same individuals by 200 Gm. of glucose, and Williams and Dyke¹⁰ found a difference in the glucose tolerance curves obtained with 50 and 100 Gm. of glucose in 3 patients with myasthenia gravis.

Chart 1.—Glucose tolerance curves on capillary blood.

Chart 2.—Glucose tolerance curves on venous blood.

Although the individual curves of the controls receiving 100 Gm. of glucose show variations,* the composite curves are similar to those produced by 50 Gm. and give little evidence of a more prolonged hyperglycemia with 100 than with 50 Gm. of glucose.

The composite curves following 100 Gm. of glucose in patients tend to remain somewhat elevated during the second and third hours as compared with 50 Gm. (Table I and Charts 1 and 2). Thus, in the capillary bloods the final values with 100 Gm. average about 25 mg. per cent above the corresponding values with 50 Gm.; in the venous bloods, they average about 14 mg. per cent higher. This slight prolongation of the hyperglycemia with 100 Gm. is also evident when the final blood glucose values are compared with the initial values: at the 50 Gm. level only one patient had a higher final than fasting blood sugar (J. B. on venous and capillary blood); at the 100 Gm. level, 6 patients had higher final than fasting values (N. P., J. M., F. B., and N. M. on venous and capillary blood; J. B. and R. B. on capillary blood only). While the two levels of glucose gave somewhat different results in the patients than in the controls, the number of cases is so small and the variations from individual to individual are so marked that one cannot say whether these different results are merely chance or are indicative of a somewhat prolonged hyperglycemia at the higher glucose level.

Zigzag curves, usually less marked than those described by Morgulis and Spence² in patients with dystrophia myotonica, occurred among both controls and patients. Although somewhat more numerous in the patients than in the controls, their rather frequent occurrence in routine glucose tolerance tests indicates that these curves are of no special significance in dystrophia myotonica.

TABLE II
AVERAGE CAPILLARY-VENOUS BLOOD GLUCOSE DIFFERENCES

SUBJECTS, DOSE	FASTING	30	60	90	120
Controls, 50 Gm.	0.2*	22.2	24.5	9.0	1.0
Controls, 100 Gm.	0.5	25.4	24.4	18.2	5.2

Patients, 100 Gm.	-0.5	24.6	23.3	21.6	14.0

*Blood values as milligrams per cent at minutes noted.

Capillary-Venous Differences.—Our data for the capillary-venous blood sugar differences show practically identical results for both patients and controls after the ingestion of 50 Gm. of glucose (Table II). In both cases the differences are zero or very small at the fasting level; they rise to an average maximum of about 25, with a range of 18 to 31.8 mg. per cent during the first hour, as a rule, and then approach zero at the end of the third hour. These figures are almost an average for the arterial-venous differences reported in the literature (Foster;^{14, 19} Lundsgaard and Holbøll;²⁰ Rabinowitch;²¹ Frieden-son, Rosenbaum, Thalheimer, and Peters;²² and Cavett and Seljeskog²³). With 100 Gm. the capillary-venous differences decline to their original level somewhat more slowly, especially in the case of the patients (see Charts 1 and 2); how-

*In considering our data on the two levels of glucose, care must be taken to compare venous values with the corresponding venous values; the same is true of the capillary values; obviously the latter will be much higher throughout the hyperglycemia than the former.

ever, no statistically significant difference is evident between the controls and the patients receiving 100 Gm. of glucose. One control showed the maximum difference at the end of the second hour in both tests; one patient (J. B. at 100 Gm.), the most severely affected clinically, showed a progressively increasing difference through the third hour—a result of special interest, since no capillary-venous difference might have been expected if severe muscular atrophy were a factor in limiting this difference.

SUMMARY

Glucose tolerance tests were performed on 7 patients with dystrophia myotonica and on 6 controls. In each patient the test was performed once with 50 Gm. of glucose and once with 100 Gm., and in each test both capillary and venous blood were examined.

The fasting blood sugars and the glucose tolerance curves were normal in all patients; no glycosuria was evident. Composite glucose tolerance curves showed slight differences between patients and controls: (1) The glucose tolerance curves were slightly flatter in the patients than in the controls (2) The composite curves for 100 Gm. tended to remain elevated in the patients at the second and third hours, especially in the capillary blood. (3) The capillary-venous differences remained slightly higher in patients than in controls receiving 100 Gm. of glucose. None of these differences was great enough to be statistically significant, and no correlation was found between variations in response to the tests and the severity of the disease.

Since marked dysfunction of the islands of Langerhans, the anterior pituitary gland, or the adrenal cortex is usually reflected in the fasting blood sugar and in the sugar tolerance curve, the results obtained furnish some evidence against a marked involvement of these endocrine glands. The removal of glucose from the capillary blood by the tissues, as indicated by the capillary-venous differences, also appears normal. It may be concluded that the mechanisms controlling the disposal of ingested glucose in dystrophia myotonica are normal.

We wish to express our appreciation to Dr. James J. Waring for pointing out the value of the glucose tolerance test in dystrophia myotonica and to him and Dr. Robert C. Lewis for their many helpful suggestions during the progress of this work and the preparation of this manuscript.

LABORATORY METHODS

GENERAL

A VESSEL FOR THE MEASUREMENT OF pH AND OXIDATION-REDUCTION POTENTIAL OF BACTERIAL CULTURES*

F. LYLE WYND, PH.D., URBANA, ILL., AND
PHILIP L. VARNEY, PH.D., ST. LOUIS, MO.

THE determination of the changes of the pH and the oxidation-reduction potential which a culture of bacteria undergoes during the course of its metabolism is of considerable interest to workers concerned with the problem of the physiology of bacteria. The difficulty of following these changes over more or less lengthy periods of time without the danger of contamination has interested us in designing the culture vessel described below.

The details of construction are evident in Fig. 1, and consist essentially of three electrodes, calomel, glass, and platinum, sealed in a No. 40 standard taper, pyrex inside joint by means of red sealing wax. These electrodes dip into the bacterial culture contained in the vessel constructed from the outside member of a No. 40 standard taper ground joint. By appropriate means the pH may be obtained from the voltage difference between the glass and calomel electrodes. The oxidation-reduction potential may be measured by using the calomel and platinum electrodes; or under special conditions, by the glass and platinum electrodes described by Wynd.³

Electrode 1 is a saturated potassium chloride: calomel half cell. The side arm *G* passes through the base of the standard joint, as indicated, and dips into the culture. The contact *H* is made through a small piece of porcelain bacteriologic filter candle sealed into the end of the tube *G*.

Electrode 2 is a double shank glass electrode constructed as described by Varney.² The bulb is filled with 0.1 N hydrochloric acid and contains a silver: silver chloride electrode whose external contact is indicated by the numeral 2 in the figure. The silver wire passes through a small glass tube of about 3 mm. outside diameter, which is sealed into the inner tube *B* of the glass electrode by red sealing wax. *C* is the outer shank of the glass electrode unit by means of which a very high degree of electrical insulation is obtained.

Electrode 3 furnishes the platinum surface *D*, whose simple construction requires no comment.

The culture vessel itself contains about 50 c.c. of bacterial suspension. The side arm *O* may be closed with a cotton plug, or a steel ball bearing may be inserted to permit anaerobic conditions and allow for the escape of carbon

*From the Department of Botany, University of Illinois, Urbana, and the Washington University School of Medicine, St. Louis.

This work was supported from a grant by the Rockefeller Foundation to Washington University for research in science.

Received for publication, June 17, 1940.

dioxide. It is necessary first to clear the culture vessel of oxygen by passing nitrogen through the apparatus by means of the opening in the plug of stopcock *N*. The degree of anaerobiosis obtained is sufficient for many types of bacteria. Side arm *P* and stopcock *N*, are so constructed as to permit the removal of uncontaminated drops of the culture at intervals without disturbing the electrode arrangement. Various types of side arms may be constructed for the practical manipulation of various types of experiments.

Fig. 1.—Culture vessel and arrangement of the electrodes. 1, Contact of the calomel half cell; 2, contact of the glass electrode; 3, contact of the platinum electrode; A, capillary tube filled with red wax and carrying the silver wire into the bulb of the glass electrode; B, the inner shank of the glass electrode which seals the outer shank C at the base; D, bulb of the glass electrode containing 0.1 N hydrochloric acid; E, rubber bulb closing the calomel half cell; F, the calomel half cell; G, side arm of the calomel half cell filled with saturated potassium chloride containing crystals of potassium chloride; H, piece of porcelain filter candle sealed into the glass side arm of the calomel half cell; I, shank of the platinum electrode; K, platinum foil; L, inside member of a No. 40 standard taper ground joint; M, outside member of the ground joint; N, ungreased stopcock; O, ball bearing or cotton plug; P, cup protecting the enclosed tip from contamination.

The technique of operation is simple but must be carefully done. The vessel *M* and its side arm *O* are plugged with cotton and autoclaved. The structure *L* is sterilized by dipping it into a solution of calcium hypochlorite for a few seconds, washed with sterile water, and placed in sterile water in a duplicate vessel *M* until ready for use. It is advisable to permit the electrodes to stand in the sterile water overnight in an incubator at 37° C. to insure the complete removal of the calcium hypochlorite from the electrically active surfaces. The culture is next added to the vessel, and the electrodes are quickly inserted.

The series of culture vessels is then connected to the proper contacts by hooking the wires 1, 2, 3, shown in Fig. 1 over the spring brass wires shown in Fig. 2. This device is constructed on a bakelite base and the electrical contacts are screwed to the upper ends of six inch polystyrene insulators. (The wiring is arranged as shown in Fig. 3.) The calomel contact 1, in Fig. 1, hooks over the spring wire *P*, the glass electrode contact 2, in Fig. 1, hooks over wire *G*, and the platinum electrode contact 3, in Fig. 1, connects to the spring wire *C*.

Fig. 2.—Series of electrode contacts within the incubator.

Fig. 3.

Fig. 4.

Fig. 3.—Wiring diagram of the electrode platform shown in Fig. 2

Fig. 4.—Incubator chamber, showing the arrangement of the control switches and the leads to the amplifier.

The complete electrode platform rests on porcelain insulators inside the incubator shown in Fig. 4. This incubator chamber is constructed of sheet iron or duralumin. The Federal Switches shown in Fig. 4 are those indicated as 1, 2, 3, 4, in Fig. 3. The common lead from the four calomel electrodes is attached to the control grid of a vacuum tube amplifier by passing through a pyrex tube, as shown on the end of the incubator. The common lead from the central contact of the four Federal Switches, as shown in Fig. 3, is brought to the proper terminal of the amplifier by means of the porcelain insulator shown on the end of the incubator.

The current from the various pairs of electrodes is amplified by the usual vacuum tube apparatus, and the voltage is read from a potentiometer. The type of amplifier described by Skow and Wynd,¹ and by Wynd and Varney,⁴ functions very satisfactorily when used in this manner.

Examination of Figs. 3 and 4 shows that the pH, or the oxidation-reduction potential of any of the four cultures may be obtained conveniently by the proper manipulation of the Federal Switches and by the observation of the corresponding voltage. By means of this apparatus we have successfully followed the changes in pH and the oxidation-reduction potential of bacterial cultures over periods as long as six days.

SUMMARY

1. The pH and the oxidation-reduction potential of a series of bacterial cultures may be observed over comparatively long periods, without disturbing the cultures, by means of a series of vessels within a metal incubator, each containing a glass, platinum, and calomel electrode, properly connected to a vacuum tube amplifier through the wall of the incubator.

2. Observations have been obtained successfully over periods as long as six days without removing the cultures from the incubator.

A SIMPLIFIED WESTERGREN SEDIMENTATION RATE TECHNIQUE

ALFRED M. GLAZER, CINCINNATI, OHIO

THE Westergren sedimentation tube has been modified by various people to facilitate the technique of the test. All of the modifications, however, require extra apparatus, such as stopcocks, racks, or special pipettes. We have been using a technique that in our opinion is simpler, requires no additional parts, except a rubber diaphragm, and is accurate.

TECHNIQUE

The diaphragm used is simply the rubber bulb of a small dropper, such as the one supplied with sample nose drops. The end of the rubber bulb is cut off and the base is placed over the bottom of the Westergren tube. The blood is drawn from the vein in the usual manner, and the proper amount of anticoagulant is then drawn into the same syringe. Then after introducing some air, the blood and anticoagulant are mixed by gentle agitation of the syringe. The

mixture is then introduced into the Westergren tube by inserting the needle through the rubber diaphragm. By using this technique the level of the blood in the tube can be carefully regulated. On withdrawal of the needle the rubber diaphragm seals itself off. With this procedure the intermediate steps between

Fig. 1—A, Sample dropper showing line of cut. B, Tube held on wall with staples. C, Technique of injecting blood into tube

taking the blood and its introduction into the tube are simplified. The tube is then held on the wall by two staples. The tube rests on the lower staple while the upper one assures the exact vertical position of the tube. The advantage of hanging the tube on the wall in this manner is its simplicity and its safety from any agitation which would invalidate the test. This technique is simple in procedure, costs nothing, and is accurate.

A MODIFICATION OF THE GRAM STAIN*

EMIL WEISS, M.D., PH.D., CHICAGO, ILL.

NUMEROUS modifications of the Gram stain have been recommended since the publication of the original method.¹ These attempts can be appreciated for the following reasons: (1) The Gram stain is an important and frequently used procedure; (2) the results vary when the same method but different ingredients are used; (3) the outcome depends to some extent upon the skill and experience of the workers. Some of the more recently used modifications^{2, 3} proposed a far more complicated technique in an effort to overcome some previous complaints and handicaps. However, they still retained a few of the previous disadvantages, especially the instability of the ingredients.

I thought it worth while to utilize my experiences with the Gram stain and to devise a procedure which would be more accessible to the average laboratory worker for the daily routine.

Generally one of the most frequently observed difficulties for the ordinary worker represents the time factor of decolorization. Ninety-five per cent alcohol decolorizes too slowly, and acetone decolorizes too rapidly. Probably the next complication in importance for the less experienced worker consists of over-staining with the counterstain. This difficulty can be more easily overcome by using weaker staining solutions for a shorter period of time. The next important obstacle consists of the staining of smears which are not uniformly and usually too thickly spread. In order to decolorize the thicker portions sufficiently, the thinner parts are too extensively decolorized, thus sometimes confusing a proper interpretation of the findings. A too concentrated solution of gentian violet may not keep and might form a sediment; a too weak solution may not produce the desired results. The same observation applies to similar dyes which are occasionally used instead of gentian violet. The ordinary Gram's iodine gives quite different results, depending upon whether the gentian violet: (1) was just poured off, (2) was washed off with water, (3) was washed off with Gram's iodine, or (4) was washed off and dried preceding the application of Gram's iodine. Apparently a prolonged application of gentian violet and Gram's iodine in excess of three minutes has very little additional effect on the results.

Our own experimental work considered the following factors: (1) concentration and stability of the used ingredients; (2) temperature of the solutions at the time of application; (3) application of additional solutions preceding the use of Gram's iodine in order to intensify the staining of gram-positive bacteria; (4) selection of a satisfactory decolorizant; (5) most effective counterstain.

It was found that a 3 per cent solution of gentian violet in a 20 per cent alcoholic solution (gentian violet 3 Gm., 95 per cent alcohol 20 c.c., distilled

*From the Department of Pathology, Bacteriology, and Public Health, University of Illinois College of Medicine, Chicago.
Received for publication, June 25, 1940.

water 80 c.c.) keeps well. Similarly, a twenty times increased concentration of Gram's iodine (20 Gm. of iodine, 40 Gm. of potassium iodine, and 300 c.c. of distilled water) also keeps well and has an increased effect over the ordinary Gram's iodine. Fuchsin was preferred to safranin on account of its bright color. A 2 per cent solution of basic fuchsin in 95 per cent alcohol was found satisfactory, stable, and preferable to other dyes. This stain should be diluted 1:4 with distilled water previous to its use. After considerable experimentation acetone was found to be the most effective decolorizant. Steaming with gentian violet for one minute and subsequent steaming with concentrated Gram's iodine for the same length of time was found slightly preferable to the same procedure without steaming. A series of 10 per cent salt solutions were tried on the smears following the washing off of the gentian violet. A freshly prepared 10 per cent solution of sodium carbonate was found to be very satisfactory; however, the advantage was not sufficiently great to include this step in the proposed procedure.

Consequently the following modification of the Gram stain has been devised:

- (1) Prepare smears as thinly and uniformly as possible and fix them over the flame.
- (2) Cover the slide with 3 per cent gentian violet for three to five minutes.
- (3) Wash with warm water.
- (4) Cover with twenty times concentrated Gram's iodine for three to five minutes.
- (5) Wash with warm water.
- (6) Cover (decolorize) the slide with acetone and wash off immediately with water.
- (7) Counterstain briefly (on and off) with above dilution of fuchsin.
- (8) Wash with water, allow to dry, and examine under oil immersion.

DISCUSSION

The proposed modification compares favorably with a number of recently recommended procedures. All the reagents are easily prepared, keep for an indefinite period, and are applied without difficulty. Repeated filtrations and waste of the deteriorated reagents are avoided. Mixing of reagents or other technical steps preceding each individual staining are not required in this technique. The technique of preparing or applying the reagents does not require any particular skill. The differentiation between gram-positive and gram-negative bacteria is very marked. Smears from tissue discharges and those from cultures give equally good results. No sediment is found in the stained preparations. This procedure has been tried out with satisfactory results on a large number of bacteria. The tested bacteria included, among others, various pathogenic and nonpathogenic cocci, intestinal bacteria, diphtheria bacilli, and several anaerobes.

SUMMARY

The proposed modification of the Gram stain offers a number of definite advantages: (1) All reagents keep well. (2) The technique is simple and is easily carried out. (3) The distinction between gram-positive and gram-negative bacteria is very distinct.

A GLASS-CAPSULE MANOMETER FOR RECORDING THE BLOOD PRESSURE*

FREDERICK F. ANDERSON, NEW BRUNSWICK, N. J.

VARIOUS methods of recording the blood pressure continuously in acute experiments in mammals have included the use of glass membranes as in the apparatus of Broemser.¹ The apparatus to be described here has certain advantages, among the more important of which are its sturdiness and sensitivity without the objectionable inertia of the mercury manometer.

Fig. 1.

Fig. 2.

DESCRIPTION OF APPARATUS

Except for the writing lever and its supports (*I*, *J*, and *K*, Figs. 1 and 2) and the springs, *L*, the apparatus is made entirely of pyrex glass. The heavy-walled chamber *A* is attached to side limbs *B*, so that bubbles may be easily removed. It has been our practice to connect one limb of *B* to a modified Trendelenburg² mercury-sodium carbonate pressure system and the other limb to the arterial cannula. The whole system, including chamber *A*, is filled with

*From the Division of Pharmacology, the Squibb Institute for Medical Research, New Brunswick.

Received for publication, June 21, 1940.

0.1 M sodium carbonate. Capsule *C*, enclosed in chamber *A*, opens into the ground joint *D* and is supported by the U-shaped rod *E*. The glass of the capsule is 0.5 to 0.75 mm. thick. The recording device consists of cylinder *F*, fitting into the ground joint *D*, the attached stopcock *G*, piston *H*, lever *I*, support *J*, and lever stop *K*. Springs *L* firmly hold the recording device in place.

Capsule *C*, the capacity of which is about 7 c.c., is filled with distilled water. There must be no bubbles of air either in capsule *C* or in chamber *A*. If the apparatus is used under conditions causing rapid evaporation of water, a few drops of watchmaker's oil may be placed on top of the piston. Chamber *A* is filled with 0.1 M sodium carbonate (or other anticoagulant) and connected with the arterial cannula and the Trendelenburg apparatus. Stopcock *G* is opened and the writing lever is pressed down to lever stop *K*. This is the base line. The stopcock is now closed, the stopper is placed in the arterial cannula, and the artery clamp is removed. Ordinarily we have adjusted the apparatus so that a movement of 5 mm. corresponds to a pressure change of approximately 10 mm. of mercury. Exact calibration is, of course, done and accurately reproducible.

The error caused by changes in temperature is small; at approximately room temperature, each change of 1° C. is followed by a pressure change corresponding to 0.8 mm. of mercury.

A CLOSED-CIRCUIT METABOLISM APPARATUS FOR STUDYING OXYGEN CONSUMPTION OF CONTROL AND THYREOACTIVATOR-TREATED GUINEA PIGS*

HARRY A. TEITELBAUM AND O. G. HARNE, BALTIMORE, MD.

A METHOD that is both simple and rapid was devised to study oxygen consumption in small laboratory animals. The entire outfit can be assembled from apparatus available in most laboratories, thus making it easy to acquire and maintain as many sets as required.

A description of the apparatus and reports of oxygen consumption in control and treated guinea pigs follows:

The metabolism unit, as illustrated in Fig. 1, consists of four fundamental parts: a Mariotte or aspirator flask *a*, a graduated cylinder *c*, an animal chamber *i*, and a weighted stand *l*. With the animal resting in the hermetically sealed chamber on the wire mesh platform *j*, and with appropriate measures taken for the absorption of carbon dioxide by the soda lime *k*, the entire unit is submerged in a constant temperature water bath to the level of the neck of the Mariotte flask. At this time the clamp *c* is closed. In order to allow the ap-

paratus to come to the temperature of the bath, an hour is allowed to elapse before readings are started. During this interval a constant current of air is passed through the system by connecting outlet *h* to a suction pump, with clamp *f* open. The opening of the side arm of the graduated cylinder to which clamp *f* is attached must be extended above the surface of the water by means of tubing. It was found advantageous to bubble the air through some water in cylinder *e*, so that the rate of flow could be estimated. The animals were found to rest very quietly throughout this preliminary period using this method.

Fig. 1.—Showing the closed-circuit oxygen consumption apparatus, *a*, Mariotte flask; *b*, glass tube; *c*, rubber connection between flask and cylinder; *d*, opening of connection *c*; *e*, graduated cylinder, 200 to 250 c.c.; *f*, side arm on cylinder; *g*, rubber connection between cylinder and animal chamber; *h*, outlet of animal chamber; *i*, animal chamber; *j*, wire mesh platform for animal; *k*, soda line; *l*, weighted stand to keep apparatus submerged.

Before describing the procedure employed in taking a reading, the application of the Mariotte flask *a* deserves comment. This flask must be adjusted at a height that permits the water in the flask to rise in tube *b* about $\frac{1}{4}$ inch. The water will not flow from the Mariotte flask into the graduated cylinder until the pressure in the cylinder is decreased by the removal of oxygen from the system by the animal within the chamber. With the submerged outlet of tube *b* kept at a constant level, the pressure exerted by the receding height of the water in the Mariotte flask as it flows into the cylinder is kept constant as long as the water level in the Mariotte flask is above the opening of tube *b*. The Mariotte principle functions in such a manner that all the water above the level of the submerged opening of tube *b* serves merely as a reservoir, while the height of

the column of water that exerts pressure in the flowing system is determined by the level at which the atmosphere comes into contact with the water, i.e., at the level of the submerged opening of tube *b*. This avoids the variations that would otherwise be introduced by the gradually decreasing pressure of a diminishing column of water as it flows into the cylinder from the flask.

Fig. 2.—Graph showing the effect of daily doses of thyroactivator hormone derived from 25 mg. of dried beef anterior lobe powder on the oxygen consumption of a guinea pig

When ready to start a reading, the air or oxygen stream is stopped. Clamps *f* and *h* are closed, and clamp *c* is opened. When the animal has exhausted enough oxygen to lower the pressure inside the system, the water begins to flow from the Mariotte flask into the cylinder. After the flow has started, the height of the water in the cylinder is recorded and readings thereafter are made at any desired interval. The amount of water that flows into the cylinder is equivalent to the volume of oxygen consumed by the animal.

When the experiment is completed, clamp *c* is closed again, and clamps *f* and *h* are opened. The water is evacuated from the cylinder by applying suction to the side arm *f*, while tube *h* is open to the atmosphere. The water in the Mariotte flask is replenished from the water bath, and the oxygen supply is restored by a current of air as described. The readings can thus be repeated any number of times.

Theoretically barometric pressure corrections should be made for each reading. However, the barometric pressure changes are so slight in the case of readings of such short duration that they were found to be of very little significance in an apparatus of such large volume as that used for the guinea pigs. In studies of the oxygen consumption of salamanders using the principle described, with appropriate modifications to suit the size of the animal, Thompson and Uhlenhuth (1936) found that barometric pressure corrections were essen-

tial. Because of the small quantities of oxygen consumed, it was found desirable to take readings over six- to eight-hour periods, during which time the barometric pressure could change significantly.

An example of the results obtained with the apparatus described is shown in Fig. 2. Here the effect of daily injections of an extract derived from 25 mg. of dried anterior lobe powder (beef) on the oxygen consumption of a guinea pig is represented.

TABLE I

OXYGEN CONSUMPTION OF 15 YOUNG GUINEA PIGS

(Each value is an average of at least five readings taken on separate days.)

WEIGHT, GM.	162	145	156	132	137	160	159	146	172	150	150	172	115	147	167
SEX	M	M	M	M	M	F	F	F	F	F	F	F	F	F	F
C.C. OXYGEN SQ.M. PER MIN.	123	139	138	131	137	146	129	141	139	130	135	135	134	139	139

Table I gives records of 15 untreated guinea pigs of both sexes ranging from 115 to 172 Gm. in weight. The oxygen values are recorded in cubic centimeters per square meter body surface per minute. The experiments were done in a constant temperature bath at 31° C. Friedgood (1934), using a modified Benedict closed circuit apparatus at 32° C., obtained average oxygen values in cubic centimeters per square meter per minute of 105 c.c. for male and 99 c.c. for females. His guinea pigs, however, weighed between 400 and 650 Gm. The higher values revealed in Table I are undoubtedly due to the younger age of the animals. DuBois (1927), discussing the effect of age on metabolism, pointed out the inverse ratio existing between the two during the early periods of rapid growth.

SUMMARY

1. A closed-circuit apparatus for the study of oxygen consumption in small laboratory animals has been described. This apparatus has the advantages of simplicity and rapidity. It has been used satisfactorily with the guinea pig, rat (Krantz and others), and salamander.

2. Oxygen consumption of a guinea pig treated with thyreoactivator hormone is shown to be increased (Fig. 2).

3. Oxygen consumption of a colony of 15 young guinea pigs is shown to be comparable. No certain sex variations were observed (Table I).

A MODIFIED TUBE FOR TATTOO MACHINES*

EDWARD HOLLANDER, M.D., NEW YORK, N. Y.

TATTOO has been employed in medical practice for the correction of cosmetic defects of the skin¹ and eye, and for the marking of laboratory animals. I introduced tattoo with mercuric sulfide for its therapeutic effect in pruritus ani.^{2, 3}

In tattoo an insoluble chemical is deposited through the epidermis into the corium by means of one or more needles. The standard machine consists of an armature (*L*) which vibrates through the magnetic action of two electromagnetic coils (*M*). A needle bar (*N*) attached to the armature passes through the tube (*B*). Six to 8 needles connected to the distal end of the bar move forward and backward with a thrust of 2 mm. by the vibration of the armature. The tube is held and moved like a writing pencil, with sufficient pressure to insure the penetration of the needles into the corium without lacerating the skin.

The purpose of the treatment of pruritus ani by tattoo is to deposit mercuric sulfide uniformly throughout the corium of the involved skin. When this is done, a uniform deep red tattoo results; the itching is relieved and the skin returns to its normal texture. To obtain a uniform tattoo, I use four upstrokes with each application of the chemical. The tube is held at an angle of 30 to 45 degrees to the skin. The corium is penetrated when the needles are kept in close contact with the skin and when sufficient current is used to make the armature vibrate freely against the resistance of the skin. It is essential that the chemical be always present at the needle points, and that these points lie parallel to the surface of the skin.

The following tube has been devised to insure the presence of a chemical at the needle points of a tattoo machine and to reduce the tension on the finger that directs the needles. It consists of a piece of hollow brass (*A*) $\frac{1}{4}$ inch in diameter and $1\frac{1}{4}$ inches in length. It is split lengthwise on its upper surface and is soldered to the tube (*B*) $\frac{1}{4}$ inch from its tip.

The distal end of the brass piece (*C*) is flattened to equal the width of the needles, and projects $\frac{1}{8}$ inch forward from the soldered base. When the tube is dipped into the chemical used for tattooing, this end acts as a reservoir to feed the needles. It is then practicable to increase the number of needles to the limit of the diameter of the tube, which is 18 needles. By increasing the number of needles from the customary 6 to 8, the time required to tattoo a certain area of skin is reduced.

Where the skin is thin, it is practicable to use 18 needles to produce a uniform deposit of the chemical throughout the corium, resulting in a uniform

*From the Manhattan State Hospital, New York.
Received for publication, July 3, 1940.

deep red tattoo. However, where the skin is hyperkeratotic or leathery, not more than 8 needles should be used. I have found that the resistance of such epidermis is too great for the uniform penetration of more than 8 needles.

Fig. 1.—View of the tube and machine from the side and front.

Fig. 2.—View of the tube from the top and front.

The proximal end of the attachment (D) is opened into a smooth flange on which the thumb or index finger rests. This acts as a fulcrum to balance the weight of the machine (8 ounces) which reduces the pressure that the finger must exert to direct the needles on the skin. Preventing fatigue of the fingers is especially important in tattooing an irregular surface, such as the perianal region, for the direction of the needles must be changed frequently to keep their points parallel to the plane of the skin.

CHEMICAL

THE ALCOHOL OF THE LUNG AIR AS AN INDEX OF ALCOHOL IN THE BLOOD*

H. W. HAGGARD, M.D., L. A. GREENBERG, PH.D., D. P. MILLER, M.S.,
AND R. P. CARROLL, NEW HAVEN, CONN.

THE concentration of alcohol in the blood is now frequently determined from the concentration of alcohol in the air of the lungs. The values so obtained are used, not only as evidence of intoxication for the police court, but also as the basis for studies in regard to the drinking habits of motorists.

It is certain that the concentration of alcohol in the lung air varies directly with that in the blood. But there are differences of opinion as to the correct figure for the coefficient of distribution; that is, the figure by which the amount of alcohol in 1 c.c. of air should be multiplied to give the amount in 1 c.c. of blood. There is also a difference of opinion as to the procedure for determining the concentration of alcohol in the lung air. Uniform results are not obtained with the various methods now in use. This paper presents a critical study on both points.

The results obtained indicate that the coefficient now commonly employed is incorrect,¹ that the method now chiefly used for collecting lung air¹ does not give a correct value for the alveolar concentration of alcohol, and that consequently the results obtained for concentration in the blood and employed for juristic and statistical purposes may be correspondingly erroneous.

In 1934 two of us (H. W. H. and L. A. G.²) determined the coefficient of distribution of alcohol between air and water as 1:1,456 at 37.5° C., which we took as the temperature at which the distribution occurred in the lungs; we determined the coefficient for air and blood at the same temperature as 1:1,150. Harger, Lamb, and Hulpieu,¹ for an apparatus called the "drunkometer," chose a value of 2,000 for the coefficient of distribution of alcohol between air and blood. Haggard, Greenberg, and Cohen³ in turn criticized the accuracy of this procedure, both because of the high coefficient and because expired air was collected in a rubber bag. They were certain, from their own experience, that such collection led to the loss of considerable quantities of alcohol, and were of the opinion, but incorrectly as is here shown, that the loss was primarily by diffusion. In studies in which alveolar air was used in determining the concentration of alcohol in the blood, they were forced to employ trained persons who exhaled true alveolar air directly into the train of the analyzer.³ At that time this was the only method by which they were able to

*From the Laboratory of Applied Physiology, Yale University, and the Connecticut State Department of Police.

Received for publication, June 7, 1940.

obtain, with the low coefficient which they employed, correct values for the concentration of alcohol in the blood as shown by direct determination from the blood.

In the course of the present study we have uncovered a feature which has not been previously taken into consideration in determining the concentration of alcohol in the blood from the concentration in the lung air, and which affords, in part at least, an explanation for the discrepancies between the coefficient used by two of us (H. W. H. and L. A. G.) and the one used by Harger, Lamb, and Hulpieu.¹ It is the retention of alcohol in the film of moisture which condenses on the surfaces of tubes and containers used in collecting expired air. When expired air at body temperature is cooled to room temperature in any container, water vapor condenses immediately as a mist, the particles of which rapidly coalesce to form a film on the inner surface of the container. The particles of the mist provide a large surface which permits a rapid equilibrium between the water and the alcohol vapor in the air. This equilibrium is established at a lower temperature, and, therefore, at a higher coefficient of distribution, than at body temperature. Although the total amount of water separated from the air is small, the high solubility of alcohol in water causes a marked reduction in the amount of alcohol in the air from which it condenses. The concentration in the air, as determined by analysis, is correspondingly lower than that which was actually present in the air before it left the lungs.

Since this feature, which must be considered in handling alcohol vapor, was unrecognized by two of us (H. W. H. and L. A. G.²) at the time we determined the coefficient distribution of alcohol between air and water and air and blood,³ these values have here been redetermined over a range of temperature from 20° to 40° C.

1. COEFFICIENT OF DISTRIBUTION OF ALCOHOL BETWEEN AIR AND WATER

The apparatus used in determining the coefficient of distribution of alcohol between air and water is shown in Fig. 1A. A stream of air flowing at the rate of 500 c.c. per minute, as determined by the calibrated manometer *M*, is washed through a saturated dichromate solution in concentrated sulfuric acid and passed successively through flasks *A*, *B*, *C*, and *D*, each containing 2 liters of alcohol solution of approximately 1 Gm. per liter. Dispersion of the air at the outlets in the flasks is obtained with fine earbonndum bubblers. The flasks, with all connections and stopcocks, are completely immersed in a water bath held at the desired temperature. The syringes, *E* and *F*, mounted on flasks *C* and *D*, permit withdrawal of water to determine the alcohol content by analysis. Flask *D* is open to the room through tube *G* which has a large bore; the pressure of air in flask *D* is not measurably above that of the room during the flow of air. The pressure in flask *C* can similarly be reduced by opening stopcock *I* when samples of air or water are withdrawn for analysis.

In determining the content of alcohol in the air of flask *D*, a measured volume of air at the rate of approximately 100 c.c. per minute is drawn through stopcocks *H* and *O* through an iodine pentoxide analyzer train.⁴ The volume of air passed through the analyzer is measured at atmospheric pressure and room temperature, but is corrected to the temperature in flask *D*.

An important feature of the apparatus shown in Fig. 1 is the provision made for evaporating condensed water vapor from the capillary tubes leading to the analyzer train. The condensate which forms, when the temperature of the bath is higher than that of the room, may hold considerable quantities of alcohol. After the desired amount of air for analysis is drawn through stopcock *II*, this stopcock is closed and stopcock *O* is turned so that a stream of fresh air will pass through the tube to the analyzer train. Any water which has condensed is evaporated and, together with the alcohol which it holds, is carried into the analyzer.

Fig. 1.—Apparatus for determining distribution of alcohol between air and fluids.

Completeness of equilibrium of alcohol between air and water in flask *D* was taken to exist when the concentration of alcohol in the air of flask *C*, as shown by analysis, corresponded exactly with that from flask *D*. In determining the coefficient of distribution at any temperature, the concentration of alcohol in the air of flask *D* is determined, and simultaneously water is withdrawn with syringe *E* and measured amounts are analyzed for alcohol. The calculation of the ratio is made as

$$(1) \quad 1: \frac{A' V}{A V'},$$

in which *A* is the amount of alcohol in milligrams in the air drawn through the analyzer train; *V*, the volume of air in cubic centimeters corrected to the temperature in flask *D*; and *A'*, the amount of alcohol in milligrams in the volume

of water, V' , in cubic centimeters, taken for analysis. Fig. 2 gives the values obtained for temperatures from 16.5° to 40° C.

Fig. 2.—The distribution of alcohol between air and water, and between air and blood. Concentration of alcohol 0.06 to 0.30 per cent.

It should be possible to calculate the coefficient of distribution of alcohol between air and water from the values given in the literature for the vapor pressure of alcohol over mixtures of alcohol and water. These determinations have, however, been made with mixtures containing 10 per cent or more of alcohol by weight. The concentration found in the blood rarely exceeds 0.5 per cent. At temperatures as high as 40° C. the coefficient of distribution is considerably affected by such changes in concentration as that between 0.5 and 10 or 20 per cent. The coefficient of distribution is calculated from the vapor pressure from the ratio:

$$(2) \quad 1: \frac{10 Pd \times 76 \times 22.4 (273 + t)}{46 pp \times 273},$$

in which P is the per cent by weight of alcohol in the mixture; d the density of the mixture at temperature t ; and pp the partial pressure of the alcohol vapor over the mixture at this temperature. At 39.76° C., Wreusky⁵ gives the vapor pressure of alcohol over water containing 42 per cent by weight of alcohol as 63.0 mm.; 22 per cent as 44.55 mm.; 18.25 per cent as 40.1 mm.; and 15.92 per cent as 37.1 mm. The coefficients of distribution as calculated from these values are 1:2,590, 1:2,000, 1:1,865, and 1:1,760, respectively. From three determinations made at 40° C. on water containing 0.01 per cent of alcohol, we find coefficients (Fig. 2) of 1,580, 1,631, and 1,638.

2. COEFFICIENT OF DISTRIBUTION OF ALCOHOL BETWEEN AIR AND BLOOD

In determining the distribution of alcohol between air and blood, the apparatus shown in Fig. 1B is used in addition to that shown in Fig. 1A. The entire apparatus is immersed in the water bath of apparatus in Fig. 1A. Bulb *P* is of 100 c.c. capacity and is fitted by long ground joints, *Q* and *R*, to tubes *S* and *T*. Tube *S* is connected under water to tube *U* of apparatus 1A, and a stream of air containing alcohol vapor from the flasks *A* to *D* is passed through bulb *B* at the rate of 750 c.c. per minute and discharged through tube *T*. Two cubic centimeters of blood are delivered into the bulb through tube *V* which projects to the middle of the bulb and is closed by a glass-tipped stopper. The bulb is rotated at the rate of 10 to 15 r.p.m.; the blood is thus spread in a thin film on the wall of the bulb for equilibration with the air containing alcohol.

Fig. 3.—The concentrations of alcohol in air and blood during equilibration in apparatus shown in Fig. 1A and B.

There is no evaporation of the blood since the air-leaving flask *D* is fully saturated with water at the temperature of the bath. In withdrawing blood for analysis, the rotation of the bulb is stopped with tube *V* in a vertical position, as shown, and projecting above the level of the water in the bath. Blood collects in the depression *W* and is withdrawn with a pipette inserted through tube *V*. Affluent air of the bulb is obtained for analysis through stopcock *H* of apparatus in Fig. 1A and effluent air through stopcock *T*. Precautions are taken, as described, to remove condensed water vapor.

In determining the distribution of alcohol between air and blood, the flow of air was continued for ninety to one hundred and twenty minutes. In order to be certain that equilibrium was complete, analyses were made at intervals of the alcohol in the water of flask *D*, in the affluent and effluent airs of bulb *P*, and in the blood. The values obtained in one such determination are shown in Fig. 3. Equilibration was complete here in sixty minutes. As a further

check upon the accuracy of the method used, a series of determinations was made with water instead of blood; the values obtained corresponded exactly with those determined as described in the previous section and given as the curve for water in Fig. 2.

Fig. 2 gives the values obtained for the coefficient of distribution of alcohol between air and blood at temperatures of 20° to 40° C. The values at 35° and 40° C. are 1:1,550 and 1:1,124, respectively. The values previously determined by two of us (H. W. H. and L. A. G.²) for these temperatures are 1:1,204 and 1:1,130. The value of 1:2,000, employed by Harger, Lamb, and Hulpieu¹ corresponds, from our determinations here, to a temperature of 31° C.

This value of 1:2,000 was not determined in vitro by Harger, Lamb, and Hulpieu, but is that given by Liljestrand and Linde.⁶ These latter investigators obtained the value empirically from determinations made on expired air and blood. No consideration was given to the loss of alcohol in condensed water vapor in collecting the air. Moreover, they are of the opinion that mixed expired air and alveolar air contain the same amounts of alcohol, a feature which Harger, Lamb, and Hulpieu were unwilling to accept, although they employed their coefficient of distribution.

3. CONCENTRATION OF ALCOHOL IN THE ALVEOLAR AND VENOUS AIRS

It is difficult to obtain on untrained subjects, particularly if they are partially intoxicated, a reliable sample of alveolar air. For these reasons, Harger, Lamb, and Hulpieu¹ collected mixed expired air, determined both the concentration of alcohol and the per cent of carbon dioxide, and converted the former to what they assumed to be the alveolar concentration of alcohol on the basis of a constant 5.5 per cent of carbon dioxide in alveolar air. This procedure involves the assumption that carbon dioxide and alcohol diffuse with equal rapidity into the air of the respiratory dead space, an assumption which we shall later demonstrate to be incorrect. In obtaining the alveolar concentration of alcohol we³ have previously employed trained subjects and taken, as alveolar air, the last third of expiration as in the method of Haldane and Priestley.⁷ We find now that this procedure is unnecessary and that the venous air⁸ obtained by a short period of rebreathing gives, for both trained and untrained subjects, a concentration of alcohol that is nearly identical with that obtained from alveolar air. These same relations have been shown previously to hold for carbon monoxide present in the blood.⁹

A consideration of the principles of elimination of alcohol shows the theoretical validity of the procedure. Because of its high solubility, alcohol is eliminated only in small amounts in the expired air; the concentrations in the pulmonary venous and arterial bloods, unlike the concentrations of carbon dioxide and oxygen, are only slightly different. The alcohol in the blood reaching the lungs is distributed between the respective volumes of air and blood in the relation of the distribution coefficient.^{10, 11} Therefore,

$$(3) \quad Ac = \frac{B + \frac{L}{C}}{V_c B},$$

in which A_c and V_c are the concentrations of alcohol in grams per liter in the arterial blood leaving the lungs and the venous blood reaching the lungs; B , the volume of blood circulated through the lungs in time t ; L , the volume of pulmonary ventilation in this time; and C , the coefficient of distribution of alcohol between blood and air with the concentration in air taken as 1.

During rest the volume of the circulation through the lungs and the volume of the pulmonary ventilation are approximately the same. On this basis, the relation between the concentrations of alcohol in the arterial and venous bloods at a distribution coefficient of 1:1,300 would be 1:1 00077 (equation 3). The error introduced in the determination of the arterial concentration would, therefore, be 0.077 per cent. Even wide variations in blood flow and volume of pulmonary ventilation would not introduce an appreciable error; thus if the ventilation were ten times as great as the blood flow, the theoretical error as calculated would be increased from 0.077 to only 0.77 per cent.

Fig. 4.—Apparatus for determining the concentration of alcohol in the alveolar and venous air

The apparatus shown in Fig. 4 is used to determine the concentration of alcohol in both alveolar and venous air. It consists of a glass tube, A , of 2.5 cm. bore, 2 meters long, contained in an asbestos lined wooden box, 15 cm. in sectional diameter. The tube projects a short distance from the ends of the box and is fitted at one end with a glass mouthpiece, B , made tight with a ground joint and removable for sterilization with dry heat. The stopcock C , of 1.25 cm. bore, is controlled from outside the box and serves to close off the tube after the sample of lung air has been collected. To prevent condensation of water vapor with loss of alcohol, as discussed in the next section of this paper, the tube is kept at a temperature slightly above 40° C. by heating coils; the current is regulated by a rheostat.

Alveolar air can be collected in the tube as in the procedure described by Haldane and Priestley.⁷ Following a normal inspiration, a deep expiration is made and stopcock C is closed. Venous air is collected by having the subject wear a nose clip and rebreathe from the tube six times; stopcock C is closed at the end of the last expiration. To determine the concentration of alcohol in the air collected, stopcock E is opened and 100 to 200 c.c. of air are drawn from the tube into the analyzer train by water displaced as described for the apparatus shown in Fig. 1A; suitable correction is made for the difference in temperature of the air in the tube and that in the room. Stopcock E is then turned to permit a flow of fresh air, obtained outside the room, to flush the tubes leading to the analyzer train and to remove any condensed water vapor. The expired air is flushed from tube A by opening stopcock C , inserting stopper F , and drawing

a brisk current of air through tube *G* which is connected to a suction pump. The apparatus described here can be assembled in more compact form by having tube *A* bent into a coil and enclosed in a square box.

Fig. 5.—Correlation between the concentration of alcohol in alveolar and venous airs.

Fifty-three pairs of comparative determinations were made of the concentrations of alcohol in the alveolar and venous airs of 5 trained subjects. They each drank from 30 to 150 c.c. of alcohol diluted to 50 per cent by volume with water. At intervals thereafter the concentration of alcohol in the alveolar air was determined and immediately following, that in the venous air. Fig. 5 presents the values obtained; each dot is made at the point of intersection of lines drawn from the ordinate value for the concentration in the venous air and from the abscissa value for that in the alveolar air of corresponding determinations. The average of all the values obtained for the alveolar air was 0.814, and for the venous air, 0.823 mg. per liter. The maximum variation in any single pair of determinations was less than 5 per cent.

4. CONCENTRATION OF ALCOHOL IN THE MIXED EXPIRED AIR

It is possible, as is demonstrated in the next section of this paper, to collect expired air in a rubber bag without appreciable loss of alcohol during the first five minutes, provided the bag is kept warmed to a temperature of 40° C. to prevent condensation. In the study here a rubber bag was placed in an incubator kept slightly above this temperature; the short glass tube leading to the bag, and used as a mouthpiece by the subject, was passed through the side of the incubator and was warmed with a small heating coil. In obtaining mixed expired air the subject, previously given alcohol, exhaled into the bag; the bag was emptied and a second expiration was collected. The mouthpiece was then closed and a measured sample of the air was drawn into the analyzer train with precautions, as previously described, to remove the condensed water vapor.

Table I gives a series of values obtained from one subject for the concentration of alcohol and per cent of carbon dioxide in the mixed expired and alveolar airs. Nine similar series made with this subject and with four other subjects gave the same results within the ordinary limits of individual variation.

TABLE I

SUBJECT GIVEN BY STOMACH 110 C.C. OF ETHYL ALCOHOL DILUTED TO 50 PER CENT WITH WATER

TIME AFTER GIVING ALCOHOL (HR.)	ALCOHOL		CARBON DIOXIDE		
	MIXED EXPIRED AIR (MG./L.)	ALVEOLAR AIR (MG./L.)	EXPIRED AIR (%)	ALVEOLAR AIR (%)	ALCOHOL IN MIXED EXPIRED AIR $\times \frac{\text{CO}_2 \text{ ALVEOLAR}}{\text{CO}_2 \text{ EXPIRED}}$ (MG./L.)
1	1.01	1.15	4.1	5.6	1.38
2	0.97	1.15	3.8	5.5	1.40
3	0.85	1.06	3.9	5.8	1.26
4	0.71	0.90	4.0	5.6	0.99
5	0.63	0.77	3.9	5.8	0.93
6	0.48	0.61	3.7	5.4	0.70
7	0.40	0.45	3.9	5.6	0.58

The last column of Table I gives the concentration of alcohol calculated for alveolar air as in the procedure followed by Harger, Lamb, and Hulpieu,¹ i.e., concentration of alcohol in mixed expired air $\times \frac{\text{CO}_2 \text{ in alveolar air}}{\text{CO}_2 \text{ in mixed expired air}}$. In each instance this calculated value is higher than that obtained by direct measurement: the average difference is 18 per cent, and the minimum and maximum differences are 9 and 23 per cent. These findings suggest that alcohol diffuses more rapidly from the surface of the respiratory passages into the air in the respiratory dead space than does carbon dioxide. The diffusion of alcohol from these surfaces does not affect the concentration of alcohol obtained directly from the alveolar or venous air, but only from the mixed expired air, approximately one-third the volume of which comes from the virtual dead space. Haldane¹² has demonstrated that the carbon dioxide which diffuses from the respiratory passages enters the mixed expired air, but not the exhaled alveolar air. In rebreathing, as in the procedure used here to obtain venous air, equilibrium of alcohol is reached throughout the entire respiratory tract. We have demonstrated that the concentrations of alcohol in the alveolar and venous airs are nearly identical (Fig. 5).

The extensive diffusion of alcohol into the air in the respiratory dead space has been previously observed by Liljestrand and Linde;⁶ they found that mixed expired air contains nearly as much alcohol as the alveolar air. As seen from the values given in Table I, the concentration of alcohol in the alveolar air is, however, higher than in the mixed expired air. The average difference is 21 per cent.

A series of experiments was carried out here to demonstrate that the diffusion of alcohol into the air of the respiratory dead space is more rapid than that of carbon dioxide. For this purpose the mouth air was used, as in the studies of Henderson and Stehle¹³ on the diffusion of carbon dioxide and oxygen. A subject, previously given alcohol, inhaled and then immediately closed off the

mouth at the pharynx and breathed through the nose. A glass tube was held between the lips, and the mouth was inflated with 75 c.c. of air by means of a hand bulb attached to the tube; the mouth was then emptied and reinflated. The air was held for two minutes, and the concentration of alcohol and the per cent of carbon dioxide in it were then determined. Immediately thereafter the concentration of alcohol and per cent of carbon dioxide in the alveolar air were determined. In a series of four such experiments the concentrations of alcohol in the mouth air were 42.4, 43.2, 41.7, and 44.9 per cent of that in the alveolar air; the per cents of carbon dioxide in the mouth air were only 16.3, 14.6, 15.1, and 17.2 of that in the alveolar air. In a second series of experiments, in which the air was held five minutes instead of two, the differences in rate of diffusion were still evident, although less marked; the average value for the concentration of alcohol was 46.2 per cent, and the carbon dioxide was 36.1 per cent of that in the alveolar air.

The concentration of alcohol in the mixed expired air is less than that in the alveolar air by approximately the same amount that it is exceeded by the concentration calculated for the alveolar on the basis of the per cents of carbon dioxide (columns 2, 3, and 6, Table I). It would appear then to make little difference, so far as accuracy is concerned, which of the two values is taken in calculating the concentration of alcohol in the blood; the error would be the same, but in opposite directions. An error of 20 per cent in calculating the concentration of alcohol in the blood from that in the lung air is probably not serious if such determinations are intended only as rough clinical approximations or are to be used, as they often have been used, in police tests to coerce the suspect into a confession of having drunk immoderate amounts of alcohol.^{1, 11}

This, however, is not the only error resulting from the procedure as now generally used. A further and widely variable error is introduced by this method of collecting the expired air and will be discussed in the following section.

5. LOSS OF ALCOHOL IN CONDENSED WATER VAPOR

When expired air is collected in containers or passed through tubes at a temperature lower than that of the body, alcohol, as we have stated, is removed in the condensed water vapor. This loss, and the corresponding error introduced into determinations of the concentration of alcohol in respired air, is not constant, but varies with the temperature of the container. The concentration of carbon dioxide in the air, because of the low solubility of this gas, is not appreciably affected by the condensation of water vapor.

The following experiments demonstrate the loss of alcohol in condensed water vapor. Air at 40° C. containing alcohol and saturated with water vapor was run from outlet *G* of flask *D*, of the apparatus shown in Fig. 1A, into a rubber bag. The bag was placed in an incubator so that it could be kept at any temperature desired. The short glass connection between the source of alcohol vapor and the bag was warmed with an electric heating coil. After 1 liter of air had been collected, the bag was emptied and again filled with this quantity of air. Samples of air were drawn from the bag at two, five, fifteen, and thirty minutes, and the concentration of alcohol was determined. The values obtained are shown in Fig. 6.

When the bag in which the air was collected was warmed to 40°C . (curve A, Fig. 6), the loss of alcohol was slow and nearly uniform; in five minutes the concentration had fallen 3 per cent, and in thirty minutes, 13 per cent. When the bag was kept at a temperature of 20°C . (curve C, Fig. 6), there was an immediate sharp drop in concentration, followed by a slow progressive drop; in two minutes the concentration had fallen 18 per cent; in five minutes, 26 per cent; in fifteen minutes, 30 per cent; and in thirty minutes, 34 per cent. When the bag was cooled to 10°C . (curve D, Fig. 6), the decreases in concentration at

Fig. 6.—Loss of alcohol from lung air in condensed water vapor at different temperatures.

the corresponding times were 28, 41, 50, and 52 per cent. In a final series of determinations (curve E, Fig. 6), the bag was first kept at 20°C . for fifteen minutes; during this time the concentration fell 32 per cent. The bag was then warmed to 40°C . to evaporate the condensed water vapor; the concentration of alcohol rose, reaching a value only 14 per cent below the initial concentration.

From the results obtained here it is evident that if expired air is collected, as is now the practice,¹ errors as great as, or even greater than, 50 per cent are to be expected. Such a collection is made from motorists at the roadside, under a wide range of daily and seasonal temperatures, and no precautions are taken to prevent condensation of water vapor from the breath. The error from condensation can be avoided only by having the receptacle in which the air is collected at a temperature sufficiently high to prevent condensation of moisture, as is done in the apparatus shown in Fig. 4.

Loss of alcohol in condensed water vapor occurs, not only when rubber bags are used to collect expired air, but also when the air is passed through glass or

metal tubes. This fact is demonstrated here by a series of determinations of the concentration of alcohol in alveolar air (Haldane and Priestley) made with the apparatus shown in Fig. 4. In separate determinations the tube was kept at 10°, 20°, 40°, and 50° C. One trained subject was used and ten determinations were made at each temperature. The coefficient of distribution of alcohol between air and blood was calculated from the concentration of alcohol obtained in the alveolar air and that in blood drawn simultaneously. At 10° C. the average value found for the coefficient was 3,123; at 20° C., 1,819; and at 40° C., 1,304. On increasing the temperature of the tube to 50° C., no further change occurred in the coefficient, which at this temperature was 1,306.

6. COEFFICIENT OF DISTRIBUTION AS DETERMINED ON 100 SUBJECTS

One hundred different subjects were either given alcohol or were brought to the laboratory after they had taken alcohol. No comparison between the concentration of alcohol in the blood and venous air was made until it was certain, from repeated determinations on the blood, that the concentration of alcohol had reached its maximum and had decreased over a period of at least one hour. This feature is important in using the concentration of alcohol in the capillary or venous blood as an index of that in the arterial blood. When absorption and distribution of alcohol are complete, the concentration of alcohol in blood from all sources corresponds closely, but prior to this time, exact agreement does not exist and appreciable errors may be introduced into the calculation of the distribution coefficient.^{2, 15}

The blood of the subjects was tested for acetone by the method described by Shipley and Long;¹⁶ no appreciable amount was found in any instance. This procedure was followed, since iodine pentoxide, used for the analysis of alcohol, reacts to acetone. In the analysis of blood the acetone can be removed with Mariott Scott-Wilson reagent,¹¹ but similar removal cannot be made from the respired air. In determinations made on more than 200 subjects given alcohol, we have found no amount of acetone in the blood sufficient to introduce any error into the determination of alcohol. An equal number of determinations made on the expired air of these subjects before they were given alcohol showed a similar absence of oxidizable material when the sample taken for analysis was not larger than 200 c.c. This result was obtained even on subjects who had eaten onions or candy containing essential oils. From them, and also from subjects with foul breath, a faint blue coloration is obtained in the starch iodide solution used for collecting the iodine liberated from the pentoxide when, and only when, more than 1 liter of expired air is passed through the analyzer train;¹⁷ this amount is five to ten times that used in the analyses reported here.

The concentrations of alcohol in the bloods of the one hundred subjects used in determining the coefficient of distribution ranged between 0.22 and 2.88 mg. per cubic centimeter. The concentration of alcohol in the venous air was determined simultaneously with that in the blood. The values calculated for the coefficients of distribution of alcohol between air and blood are shown as dots in Fig. 7. The average for the series was 1:1,307, with extremes of 1:1,180 to 1:1,307, variations of -9.7 and +8.9 per cent.

Harger, Lamb, and Hulpieu¹ have reported a similar series of determinations in which the "drunkometer" was used to obtain the concentration of alcohol in the expired air from which that in the alveolar was calculated on the basis of the per cents of carbon dioxide in expired and alveolar air. The values they obtained are shown in Fig. 7 as circles; the average value is approximately 2,000, but the extremes are 1:1,220 to 1:4,200, variations of -39 and +110 per cent. Such variations would appear extreme even for medicolegal approximations.

Fig. 7.—The coefficient of distribution of alcohol between blood and lung air. Dots, values as determined here; circles, values as reported by Harger, Lamb, and Hulpieu.

7. TEMPERATURE AT WHICH THE DISTRIBUTION OF ALCOHOL OCCURS IN THE LUNGS

The coefficient of distribution of 1:1,307, as given in the previous section, corresponds to a temperature for the distribution of 38° C. (see Fig. 2). This temperature is very nearly that of the blood flowing through the lungs.^{18, 19} No measurements have ever been made of the temperature of the air in the lungs, and few reliable ones have been made of the temperature of the air leaving the lungs when not mixed with air in the respiratory dead space. The most recent and precise are those made by Seeley.²⁰ He finds that when the air breathed is at 20° C., the temperature of the exhaled air measured at the larynx is 35° C.; when the air breathed is 10° C., the temperature of the exhaled air falls to 34° C., and when breathed at 40° C. it rises to 36° C. It is certain that the temperature of the expired air does not precisely represent that in the lungs. If it did, the air in the alveolar spaces would be indicated as having a lower temperature than the blood passing through the lungs.

The air in the respiratory dead space, which is motionless between the times of inhalation and exhalation, comes into partial equilibrium, as we have shown, with the alcohol on the surface of the respiratory passages; this alcohol appears

in the air of the first part of expiration. It is improbable, for reasons which we have previously indicated, that during expiration the rapidly moving alveolar air either receives or gives up alcohol to surface tissues which may be at a lower temperature than the lungs. We have, however, investigated this point. On rebreathing from the tube of the apparatus shown in Fig. 4, to obtain venous air, the inhaled air becomes warmed to nearly 40° C. We have already shown (Fig. 5) that the concentration of alcohol in the alveolar air, after inhaling air at ordinary room temperature, is nearly identical with that of the venous air. This fact suggests that the temperature of the expired air has no influence upon the concentration of alcohol in the alveolar air. These observations were extended to include room temperatures of 10° and 40° C. Neither temperature affected the concentration of alcohol, as determined in the alveolar air.

When the alveolar air was exhaled into the tube (apparatus Fig. 4), heated to 40° C. and allowed to remain there, no fog and no condensation occurred; when the temperature of the tube was lowered to 35° C., there was a slight, but definite, fog; and when the experiment was repeated at a temperature of 30° C., there was a heavy fog, with condensation of a film of water upon the interior of the tube. This observation indicates that the alveolar air is saturated with water vapor at a temperature above 35° C. If, then, during expiration, the air from the depths of the lungs does not lose water in the respiratory passages, even at their lower temperatures, it is highly probable that it would not lose alcohol.

More precise measurement of the water vapor was obtained by direct determination from the alveolar and venous airs. A U-tube containing 70 Gm. of anhydrous magnesium perchlorate was attached to the tube from stopcock E of the apparatus shown in Fig. 4. The glass connections were warmed with a heating coil to prevent condensation. Two hundred cubic centimeters of alveolar or venous air were drawn through the U-tube, and the gain in weight was determined. The values obtained for five determinations on one subject for alveolar air with inspired air at 20° C. were: 43.0, 43.1, 44.0, 42.6, and 43.2 mg. per liter, the average of which corresponds to the amount of water in air fully saturated at a temperature of 37.2° C. The values obtained from the venous air with the rebreathed air at 40° C. were: 41.7, 44.2, 43.2, 44.0, and 43.4 mg. per liter of air.

CONCLUSIONS

1. The coefficient of distribution of alcohol between air and blood, now widely employed, is that assigned by Harger, Lamb, and Hulpieu, viz., 1:2,000. We find that the correct value, as determined both *in vitro* and *in vivo*, is 1:1,300.
2. The discrepancy is, in part, due to the loss of alcohol in condensed water vapor in containers used to collect expired air. This loss has been demonstrated.
3. The concentration of alcohol in lung air cannot be correctly calculated from the concentration in mixed expired air on the basis of carbon dioxide content of these airs. Alcohol diffuses more rapidly into the air of the respiratory dead space than does carbon dioxide. The diffusion does not affect the concentration in the alveolar or venous air.
4. The concentration of alcohol in the venous air corresponds closely to that in the alveolar air. A method is described for obtaining venous and alveolar air without loss of alcohol.

5. The temperature at which the distribution of alcohol between air and blood takes place in the body is that of the blood in the lungs

6. The procedure now widely used in medicolegal investigation and statistical studies for determining the concentration of alcohol in the blood from that in the expired air is subject to serious errors. It is, however, possible to determine accurately the concentration in the blood from that in the lung air.

A CLINICAL METHOD FOR THE DETERMINATION OF ASCORBIC ACID IN BLOOD PLASMA AND URINE*

ELMER STOTZ, PH.D., WAVERLEY, MASS.

MINDLIN and Butler¹ have developed a method for the determination of plasma ascorbic acid, measuring photoelectrically the excess dye remaining after the reaction between ascorbic acid in a metaphosphoric acid filtrate and 2,6 dichlorophenolindophenol. In avoiding a titrimetric procedure in strong acid solution which allows considerable error due both to slow reduction by other materials and to decomposition of the oxidized dye, the method represents a real advance. The method of Bessey² extends the usefulness of this procedure by eliminating the necessity of absolutely clear and colorless filtrates. The preparation of such filtrates in the first method requires considerable care and time in filtering; in the second method two readings of the photoelectric device are necessary for each sample. In both procedures the photoelectric readings must be completed immediately after each addition of dye, with due care exercised in observing possible "drifts" of the reading due to the presence of slowly reducing materials, all of which is very time-consuming in serial analysis. The finding of Bukatsch³ that oxidized 2,6 dichlorophenolindophenol can be quantitatively extracted from acid solution with xylene has led to an accurate, rapid clinical method. The method developed includes all the advantages of the procedures described, does not require special care in the preparation of the filtrate, and requires only a single photoelectric reading for each sample. The dye is allowed contact with the ascorbic acid for the short time necessary for reaction, then extracted into xylene, where it is no longer subjected to an acid medium or to slowly reducing substances, and is, therefore, completely stable for hours. The extraction involves a simple shaking with xylene and brief centrifugation. Because of the stability feature, as many samples as desired can be treated with the dye and extracted, and when all are completed, the color of the xylene layers measured as a unit in the photoelectric device. The separation of the chemical work from the photoelectric measurements saves time in its greater convenience. The stability of the dye in xylene permits the reliable use of the visual colorimeter in the absence of photoelectric devices.

The method to be described was developed with the view of increasing the ease and speed of plasma ascorbic acid determinations in serial analysis required in a recent research project.

DETERMINATION

Apparatus and Reagents.—Any photoelectric colorimeter, or, as employed in this work, a Coleman "DM" photoelectric spectrophotometer.

*From the Biochemical Laboratory of McLean Hospital, Waverley, Mass., and the Department of Biological Chemistry, Harvard Medical School, Boston.

Received for publication, October 10, 1940.

Metaphosphoric acid. Six grams of clear sticks of glacial metaphosphoric acid, dissolved in 100 c.c. of water and filtered. This reagent is serviceable for eight to ten days if kept in the icebox.

Dye solution. Approximately 12 mg. of 2,6 dichlorophenolindophenol dissolved in 200 c.c. of warm distilled water, cooled and filtered. This reagent is satisfactory for eight to ten days if kept in the icebox.

Sodium hydroxide. An approximately 0.8 N solution made by dissolving 32 Gm. of sodium hydroxide in 1 liter of water.

Phosphate-citrate buffer. Approximately pH 4.0. Mix 30 c.c. of 0.2 M disodium phosphate and 50 c.c. of 0.1 M citric acid.

Bromeresol green 0.04 per cent. Add 14.3 c.c. of 0.01 N sodium hydroxide to 0.1 Gm. of bromeresol green and make up to 250 c.c. with water.

Xylene, C.P.

Method.—Blood for analysis should be collected (approximately 7 c.c.) with a dry syringe and kept in thoroughly clean pyrex tubes containing oxalate (about 20 mg.) as an anticoagulant. Excessive shaking and other causes of hemolysis are to be avoided. The tubes are chilled after collection and analysis is started within five hours. The blood is centrifuged and the plasma is withdrawn. Three cubic centimeters of plasma are measured into a test tube, followed by 3 c.c. of distilled water and 6 c.c. of 6 per cent metaphosphoric acid. After thorough mixing and allowing to stand for fifteen minutes, the tubes are centrifuged at 2,500 r.p.m. for fifteen minutes. The metaphosphoric acid filtrate may be kept for several hours in the cold without loss of ascorbic acid. A pipette is inserted into the supernatant fluid and exactly 8.0 c.c. of filtrate are removed to a 30 c.c. test tube. Two drops of bromeresol green indicator are added and 0.8 N sodium hydroxide is added dropwise with shaking until a green color is reached, then approximately 1 c.c. of the phosphate citrate buffer is added. Exactly 2.0 c.c. of the dye solution are added, the tube is revolved for mixing, the solution is layered with 12.0 c.c. of xylene, corked, and shaken for ten to fifteen seconds. Only fifteen to thirty seconds need elapse between addition of the dye and extraction in order to avoid slow, interfering reactions. The amount of dye prescribed in this test is sufficient to react with approximately 0.05 mg. of ascorbic acid or a plasma ascorbic acid of 2.5 mg. per cent. If more than this is encountered and the dye is completely reduced, accuracy is not sacrificed by adding a further 1.0 or 2.0 c.c. of dye at this stage. The tube is centrifuged briefly to separate the layers. Occasionally, and more often on too vigorous a shaking, the two layers do not separate well. In this case, after the first centrifugation, the xylene layer should be stirred briefly with a glass rod and again centrifuged. At the end of a series of analyses a "control" tube should be prepared, containing 8 c.c. of water, 1 c.c. of buffer, and exactly 2.0 c.c. of dye, followed by xylene and extraction.

The xylene layer may now be poured off easily and at any time within several hours into the special cells of the photoelectric device. In the case of the spectrophotometer, with xylene in the "solvent" tube, the transmission of the "unknown" and "control" tubes are determined at wave length $\lambda = 500 \text{ m}\mu$. (In the Evelyn or other photoelectric colorimeters the filter trans-

mitting maximally at 500 $m\mu$ should be used.) The difference in the logarithms of these two transmissions is directly proportional to the amount of ascorbic acid originally present, that is,

$$C = k(\log I^0/I \text{ control} - \log I^0/I \text{ unknown}) = k(\Delta \log).$$

Entirely similar relations are given in Bessey's paper for the case of the Evelyn colorimeter. The value of K must be determined only once for the prescribed conditions and for the instrument used, with a carefully weighed or iodine standardized ascorbic acid solution. Thus in this case a $\log = 0.064$ was equivalent to 0.01 mg. of ascorbic acid, hence the milligrams of vitamin C involved in a given determination would be

$$C = \frac{\Delta \log}{0.064} \times 0.01.$$

Since the 8 c.c. of filtrate represents 2.0 c.c. of plasma, then in milligrams per cent of plasma ascorbic acid

$$C = \frac{\Delta \log}{0.064} \times 0.01 \times 50 = 7.81 (\Delta \log).$$

If the visual colorimeter is used, various dye controls must be prepared as above in order to permit accurate comparison with the widely different ascorbic acid values encountered in routine analysis. Also, each dye solution utilized must be standardized against a carefully prepared ascorbic acid solution. If reduction of the amount of dye prescribed is great, more favorable colorimetry is obtained by adding a greater excess of dye. Visual colorimetry cannot, however, provide the accuracy obtained by photoelectric measurement.

TABLE I
REPRODUCIBILITY OF METHOD AND COMPARISON WITH BESSEY'S² PROCEDURE OF
PLASMA ASCORBIC ACID DETERMINATION

SAMPLE	PRESENT METHOD (MG. %)	BESSEY'S METHOD (MG. %)	AVERAGE % DIFFERENCE
Blood 1	0.74	0.77	4.6
	0.70	0.72	
	0.71	0.76	
Blood 2	1.08	1.16	4.3
	1.06	1.12	
	1.11	1.11	
Blood 3	0.38	0.41	5.0
	0.42	0.44	
	0.39	0.40	
Blood 4*	1.79	1.83	2.8
	1.82	1.88	
	1.82	1.87	

*Taken after administration of vitamin C.

The same method may be readily applied to urine. Equal volumes of freshly voided urine and 6 per cent metaphosphoric acid are mixed and filtered. An appropriate volume of this filtrate to be used may be judged by a rough titration into 2 c.c. of the dye.

The reliability of the indophenol dye-ascorbic acid reaction and recoveries obtained by its use have been amply shown.^{1, 2} It was necessary only to check on the quantitative extraction of the oxidized dye from acid solution by xylene and the applicability of Beer's law to the xylene solution of dye. Both of these stipulations were satisfied in the concentration range of dye utilized in this test. Table I illustrates the agreement of the values found on several samples of blood by Bessey's method² and the present modification.

A SIMPLE RAPID METHOD FOR DETERMINING RELATIVE BLOOD VOLUME CHANGES BY SPECIFIC GRAVITY STUDIES*

C. T. ASHWORTH, M.D., AND W. D. TIGERTT, M.D.
DALLAS, TEXAS

RECENT advances in the study and treatment of shock have made necessary a simple practical method for determining changes in blood volume during the development and treatment of that condition. We present herein a method which is thought to represent such a procedure based entirely on specific gravity determinations.

Methods that are at present in use for estimating blood volume changes uniformly depend upon the determination of the concentration of various substances in the circulating blood, and from the known total amount of that particular substance in the blood, calculating the total volume of blood therefrom. With this general principle as a common feature there are two separate, practical approaches that may be utilized. The first of these is the dye method, first introduced in 1915 by Keith, Rowntree, and Geraghty.¹ These investigators determined the blood volume from the concentration of vital red injected into the circulating blood. The most significant modification of this method has been that of Gregersen, Gibson, and Stead,² who introduced Evan's blue as the dye and determined the dye concentration by photoelectric colorimetry. Although there are disadvantages and sources of error in these methods, their use has become well established in recent years. It is, however, with the second of these general methods for determining blood volume changes that the present consideration is particularly concerned. This method takes into account the changes in concentration of red blood cells, hemoglobin, or plasma proteins. Kottman³ in 1906 was the first to utilize this principle. In more recent years a number of investigators have studied blood volume changes, particularly after injection of isotonic and hypertonic fluids, using hemoglobin changes as the basis of blood volume alternations. Most of these workers have used difficult gasometric methods for hemoglobin determination. Bogert, Underhill, and Mendel⁴ showed that the variations in hemoglobin were an accurate indication of relative blood volume change by simultaneous determinations of total solids of the blood. Smith and Mendel,⁵ Blalock, Beard, and Thuss,⁶ Miller and Poindexter,⁷ and Robertson⁸ obtained apparently good results in estimating

*From the Department of Pathology, Baylor University College of Medicine, Dallas, Texas.
Received for publication, November 19, 1940.

blood volume change by hemoglobin alterations after intravenous injections of fluids in animals. Gilligan, Altschule, and Volk⁹ used changes in the hematocrit to calculate changes in blood volume in human beings following intravenous injections of various fluids. These investigators were able to compare the results of this method with the dye method of Gregersen, Gibson, and Stead² in a few cases. They found the results to be in good accord.

Investigators, particularly Lamson and Rosenthal¹⁰ and Miller and Poin-dexter,⁷ have seriously objected to the older dye methods on the basis of inaccuracy. However, these workers failed to take into account the residual dye remaining from previous injections in repeated blood volume determinations. This source of error has been clarified by Smith.¹¹ The method of Gregersen, Gibson, and Stead² at present must be considered the most accurate means of determining a given blood volume level, but is not itself free from disadvantages and sources of error. Particularly in cases of shock and burns under clinical and experimental conditions, the curve of disappearance of the blue dye will be variable because of variable degrees of capillary damage. Under these same circumstances there will be relatively less disappearance of red blood cells from the circulating blood. Furthermore, in the use of the dye method for repeated blood volume estimations, the necessity of determining the disappearance curve in a particular subject is an almost insurmountable disadvantage in clinical shock and burns; to a less extent is this true under experimental conditions.

In studying the alterations of the blood in experimental shock in dogs, attention was called to the great practical value of estimating changes in blood volume by changes in the hematocrit. It was also found that the red blood cell percentage (hematocrit) could be accurately determined from the specific gravity of whole blood and plasma. This report is, therefore, designed to illustrate the simple and practical manner of determining relative blood volume changes from specific gravity determinations. The method is adapted only to the determination of approximate plasma volume changes, and not to the accurate determination of the blood volume level. The procedure is based on calculating the hematocrit from the specific gravity of whole blood and plasma, and determining from changes in the hematocrit, alterations in the plasma volume.

METHODS

Dogs were used in all experimental work. Anesthesia was accomplished by intravenous injection of nembutal. Blood samples were taken at varying intervals, an average of four samples for each experiment. Blood was withdrawn from exposed jugular veins so that no compression of the vein was necessary. Shock was produced by trauma to extremities, trauma to intestine, intraperitoneal injection of 25 per cent sodium chloride, or application of tourniquets to both legs with subsequent release of the tourniquets. The average duration of the experiments was nine hours. Simultaneously blood pressure was determined by mercury manometer connected with the carotid artery. Heparin was used as the anticoagulant. On all samples of blood red cell counts, hematocrits, specific gravity of whole blood, and specific gravity of the plasma were determined. The hematocrit was determined according to the method of Win-

trobe,¹² centrifugation being carried out for forty-five minutes at 3,000 r.p.m. The specific gravity of whole blood and plasma were determined by the Falling Drop Method of Barbour and Hamilton.¹³

PROCEDURE

The hematocrit may be determined by specific gravity determinations of blood if it is recognized that the specific gravity of the whole blood is dependent upon the specific gravity of the red blood cells, the specific gravity of the plasma, and the proportions of the latter two components. This fact is apparent since the specific gravity of a mixture of two solutions is proportionately dependent upon the specific gravities of the two solutions. Assuming that solution A is composed of 4 c.c. of solution B and 2 c.c. of solution C, then

$$(1) \text{ Sp. Gr. of A} = \frac{(\text{Sp. Gr. of B} \times 4) + (\text{Sp. Gr. of C} \times 2)}{6}$$

The same will be true of whole blood, as follows:

$$(2) \text{ Sp. Gr. of Whole Blood} = \frac{(\text{Sp. Gr. of R.B.C.} \times \text{R.B.C. } \%) + (\text{Sp. Gr. of Plasma} \times 100 - \text{R.B.C. } \%)}{100}$$

Solving for red blood cell percentage,

$$(3) \text{ R.B.C. } \% (\text{Hematocrit}) = \frac{(\text{Sp. Gr. of Whole Blood} \times 100) - (\text{Sp. Gr. of Plasma} \times 100)}{\text{Sp. Gr. of R.B.C.} - \text{Sp. Gr. of Plasma}}$$

It is at once obvious that for the hematocrit to be determined from equation (3), the specific gravity of whole blood, of plasma, and of the red blood cells must be known. The latter factor should be a constant, and the former two factors should be readily determinable by the Falling Drop Method. It is an easy matter to ascertain the specific gravity of red blood cells from equation (2) if the specific gravity of whole blood, specific gravity of plasma, and hematocrit are known:

$$(4) \text{ Sp. Gr. of R.B.C.} = \frac{(\text{Sp. Gr. of Whole Blood} \times 100) - (\text{Sp. Gr. of Plasma} \times 100 - \text{Hematocrit})}{\text{Hematocrit}}$$

From a series of 32 blood samples shown in Table I, taken from ten dogs selected at random from a larger series, it has been possible to determine the mean specific gravity of red blood cells to be 1.0953, with a standard deviation of 0.00205. Substituting then, 1.0953 in equation (3), it is possible to solve for the hematocrit if the specific gravity of whole blood and specific gravity of plasma are known. Table I shows that the red blood cell percentage calculated by this means differs only slightly from the actual hematocrit. To facilitate the determination of the hematocrit from the specific gravity of the whole blood and of the plasma, a nomogram, Fig. 1, has been constructed.

In using the hematocrit to estimate blood volume changes, it is necessary to determine an original blood volume by the dye method or to assume an original blood volume based on body weight. Blood volume in dogs has been estimated as 0.0915 of body weight. The total volume of red blood cells can then be determined from the hematocrit and the original blood volume:

Total R.B.C. Volume = Blood Volume (0.0915 of Body Wt.) \times Hematocrit

Assuming this total volume of red blood cells to remain constant, the resulting

blood volume can then be calculated from the subsequent hematocrits as follows:

$$\text{Blood Volume (2)} = \frac{\text{Red Blood Cell Volume} \times 100}{\text{Hematocrit (2)}}$$

In order to simplify this estimation Fig. 2 represents a nomogram which may be used to determine quickly the blood volume resulting after change in the hematocrit.

Standard deviation—0.0020 or 0.2053 per cent.

RESULTS

Using the principles indicated above, it is possible to determine relative blood volume changes in a time as short as ten minutes, most of which time required for a short centrifugation of the blood sample in order that a small amount of plasma may be obtained for specific gravity determination. In order to illustrate the manner of application and the relative accuracy of the present method, data on six dogs selected from a larger series are presented in Table II. It will be seen from the table that there is a close correlation between

Fig. 1.—Nomogram for determining hematocrit from specific gravity of whole blood and plasma. A straight line from the specific gravity of whole blood and plasma crosses the middle line at the hematocrit level.

Fig. 2.—Nomogram for determining the blood volume changes from the hematocrit. A straight line from point 0 to the blood volume crosses the horizontal line of the original hematocrit at a point where the latter is intersected by the vertical line of the red blood cell volume. Then a line drawn from 0 through the point of intersection of red blood cell volume and subsequent hematocrits, crosses the blood volume indicator at the point of resulting blood volume.

*Blood volume calculated as 0.0915 of body weight.

the actual hematocrit and the calculated hematocrit. In almost all instances the difference is not greater than the error to be expected in hematocrit determinations. Since in shock the degree of capillary damage is such that colloidal dyes escape irregularly from the circulating blood, it is not possible to check the results of this method by the usual dye methods of blood volume determination. Magladery, Solandt, and Best¹⁴ have recently pointed out the inadequacy of dye methods for blood volume determination in shock. It will, however, be noted that there is close agreement between the blood volume decrease based on these hematocrit values and the blood volume decrease expected to occur in the development of shock. This expected decrease is based on the body weight of the animals, 3 per cent of body weight or one-third of blood volume being expected to be lost when the duration of the experiment is as long as eight hours.¹⁵ The closest possible check on the method is afforded by the intraperitoneal injection of 25 per cent sodium chloride solution. Presumably all the lost plasma will be in the peritoneal cavity where it may be measured. In three dogs shown, Nos. 19, 20, and 21, it will be seen that there is accurate correlation in this regard.

DISCUSSION

In all circumstances where blood volume alteration due to increase or decrease of plasma volume occurs, these changes may be simply and accurately determined from the specific gravity of whole blood and plasma. Intermediately the hematocrit is calculated. Naturally, in those conditions where blood volume decrease is attended by an appreciable loss of red blood cells, the method will be of considerably less value. It should be remembered, however, that in those conditions where there is loss of red blood cells, the dye method will also be in error because of dye being lost from the blood stream. It would seem that wherever repeated estimations of blood volume may be accomplished by the indirect dye method, the relative blood volume changes may be computed from the specific gravity.

In experimental shock due to mild trauma to extremities, application of tourniquets, trauma to intestine, or intraperitoneal injection of hypertonic sodium chloride solutions, the method is particularly applicable. This is true because the loss of red blood cells is negligible under these circumstances.

In human beings the same methods should be applicable for determining relative blood volume changes. In a series of determinations of specific gravities of human red blood cells somewhat lower values than those for dogs have been obtained. The mean specific gravity of human red blood cells was found to be 1.0913, with a standard deviation of 0.0016. The formula for determining the red blood cell percentage (hematocrit) in man would then be:

$$\text{Hematocrit} = \frac{(\text{Sp. Gr. of Whole Blood} \times 100) - (\text{Sp. Gr. of Plasma} \cdot 100)}{1.0913 - (\text{Sp. Gr. of Plasma})}$$

Clinically, relative blood volume changes calculated from specific gravity of whole blood and plasma might be expected to be accurate in a great many circumstances. In cases of burn, where the decreased blood volume is due entirely to escape of plasma, the method should be particularly useful. This is especially true since most all cases of burn are seen quickly enough in hospitals that a sample of blood drawn on admission will reflect well the total red blood cell volume as calculated from the total blood volume determined from weight, and the red blood cell percentage determined from specific gravity of whole blood and of plasma. In the usual case of shock from trauma, operation, and anesthesia, intestinal obstruction, marked diarrhea, protracted vomiting, etc., as long as there is no excessive loss of blood, the method should be suitable. Where blood volume changes temporarily occur from injection of various isotonic and hypertonic solutions as well as whole or concentrated plasma, it will be very simple to determine these changes by changes in the specific gravity.

It should be pointed out that the specific gravity of the red blood cells of dogs and of human beings varies not only in different individuals but also in the same individual at different times. The degree of variation, however, which has so far been encountered, has not been sufficient to cause an appreciable error in the calculations. A subsequent report shall consider in greater detail the specific gravity of human red blood cells and the variation of this property under different circumstances.

SUMMARY

1. The hematocrit, or red blood cell percentage changes reflect accurately the plasma volume changes under circumstances where there is no appreciable loss of red blood cells.

2. A new, quick method for determining red blood cell percentage by specific gravity studies of whole blood and plasma is presented.

3. Blood volume changes in experimental shock due to mild trauma, intraperitoneal injections of hypertonic solutions of sodium chloride, or application and subsequent release of tourniquets may be accurately followed by this method.

4. Clinically the method should prove of value in studying the relative volume changes in shock due to trauma, operations and anesthesia, intestinal obstruction, severe diarrhea, and protracted vomiting. The same procedure should be an accurate guide to fluid therapy in shock and other conditions.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

LEVULOSURIA, Study of Two Cases in Brothers, Jacobsen, V. C. *Am. J. M. Sc.* 200: 304, 1940.

Two cases are reported of so-called essential levulosuria in young Jewish brothers. They bring the total on record to 33. The condition appears to be a metabolic anomaly in which the organism exhibits a partial or complete inability to convert levulose into glycogen. This seems to be due not to a hepatic deficiency, but to increased permeability of the kidneys by the levulose molecule. This renal hypothesis does not postulate any inherent kidney disease, although in one case with paroxysmal hypertension there were signs of renal irritation. In both cases an approximately equal amount of glucose was excreted, but only at the same time that levulose was passing through the kidneys. Normal dextrose and levulose tolerance tests were obtained.

The clinical importance of the condition lies in its early recognition, before the patient is subjected to the rigors of a diabetic regimen which may severely handicap the growing child. The treatment is reassurance that he does not have diabetes mellitus, and a diet without special restrictions. So far as is known, the passage of levulose through the kidneys causes no harm, although continual observation of these interesting people throughout their lives may later alter this dictum in some degree.

SERUM, Significance of Albumin-Globulin Ratio of, Melnick, D., Field, H., Jr., and Farnall, C. G., Jr. *Arch. Int. Med.* 66: 295, 1940

The albumin-globulin ratios characteristic of normal and hypoproteineamic sera represent the relative amounts of two independent protein systems, which may be separated by salting-out procedures. Dissociation and association phenomena attributed to the serum protein molecules must occur within these independent systems. Exposing normal and hypoproteineamic sera to the same environmental factors by dialysis of one against the other does not alter the ratio of one protein fraction to another. The influence of incipient denaturation on the salting-out behavior of the serum protein complex has been studied and serves to explain the alleged conversion of albumin to globulin reported by others. Urinary protein does not represent total serum but is derived principally from the albumin fraction.

The inadequacy of colloid osmotic pressure measurements *in vitro* and of the determinations of albumin and globulin for predicting the true oncotic pressure *in vivo* are discussed in the light of recent physicochemical studies of the serum protein complex.

PNEUMOCOCCI, Immune Reactions of Carriers and Non-Carriers of Type-Specific, Finland, M., Brown, J. W., and Barnes, M. W. *Am. J. Hyg.* 32: 24, 1940.

Cultural and serologic studies were carried out in a selected group of the personnel of the medical wards of a general hospital in which large numbers of patients with pneumonia are admitted for treatment. The studies were directed primarily to the isolation and identification of pneumococci and their types and the determination of type-specific pneumococcus antibodies.

The most efficient method found for detecting pneumococcus carriers consists of inoculating a swab of the pharynx into suitable culture media, injecting some of the growth resulting after four to six hours' incubation into a mouse and then examining the peritoneal washings after six to twenty-four hours.

Fifty-six per cent of the persons studied were found to harbor pneumococci in their pharynx on one or more occasions. The percentage of carriers detected was related to the

number of times the cultures were made. However, those in whom pneumococci were not found in the first culture were less likely to have them in subsequent cultures and, if pneumococci were acquired, they were more readily lost. The duration of the carrier state varied considerably.

The finding of pneumococci during this study was apparently unaffected by the recent presence of acute respiratory infections.

The distribution of pneumococcus types encountered showed a predominance of some types, such as III, VI, and XIII, which are usually frequent among normal healthy carriers. Twenty-six different specific types were encountered, and only 1 per cent of the strains of pneumococci failed to react with serums for types I to XXXII. In some instances mouse passage was necessary before the type could be determined.

Carriers of pneumococci frequently had, or acquired, homologous type-specific antibodies. The time of appearance of such antibodies in relation to the finding of the pneumococci, and the length of time over which the antibodies could be detected varied widely and was not always related to the duration of the carrier state.

Some indirect evidence was adduced which indicated that certain of the personnel acquired some of their pneumococci from patients under their care. In many instances, however, the findings suggested that the carriers acquired the various pneumococci from one another.

Four of the patients developed atypical pneumonia in the course of this study. Two of these were known to be chronic carriers, and the same types were found during their illness; one had a few pneumococci in his sputum during his illness but none before or later; and the fourth was a transient carrier before the onset of his pneumonia, but no pneumococci could be found during his illness. None of these four patients developed significant antibodies either to the pneumococcus which was found or to most of the common types associated with pneumonia.

These findings lend further support to the antigenicity of type-specific pneumococci in apparently healthy carriers.

The findings in the patients who developed pneumonia indicate that pneumococci found in patients with atypical pneumonias may not be etiologically related to the infection.

TISSUE: Improved Method of Staining Within Tissues, Leptotriches of Parinaud's Conjunctivitis and Gram-Positive Micro-Organisms, Verhoeff, F. H. J. A. M. A. 11 1546, 1940.

Fix fresh tissue in Zenker's solution or solution of formaldehyde.

Embed in celloidin or paraffin. Celloidin sections are the more readily manipulated.

Cut sections as thin as possible, not more than 10 microns in thickness.

Stain sections in hematoxylin and eosin.

Mount, examine, and select sections that contain the largest foci of macrophages.

By the aid of xylene remove the selected sections from the slide and wash in oil of thyme, then in 95 per cent alcohol, and then in water. (Hematoxylin may be removed by acid alcohol, but this is not necessary.) If large foci of macrophages have been found, adjacent unstained sections will undoubtedly also contain them and may, therefore, be used instead.

The solvents now to be used are placed in small receptacles, such as ordinary salt cellars. Celloidin sections are to be immersed in these. In the case of paraffin sections the solutions are to be dropped on the slides by means of eye droppers. Water is placed in large finger bowls.

Place the celloidin section from the water on a slide. Wipe away any excess of water and drop on the section Stirling's crystal violet (methyl rosaniline 5 Gm., 95 per cent ethyl alcohol 10 c.c., aniline 2 c.c., water 88 c.c.) for two minutes.

Float the section from the slide into a bowl of water. Wash in several changes of water; this requires about two minutes.

Immerse in compound solution of iodine, from twenty to sixty seconds (iodine 1 Gm., potassium iodide 2 Gm., water 100 c.c.).

Wash in water and transfer to 95 per cent alcohol. Stir the section around until the stain begins to come out freely, about five seconds.

Transfer quickly to trichlorethylene. Stir the section around until the color ceases to come out freely, about ten seconds.

Transfer to oil of thyme one minute, then to 95 per cent alcohol for five seconds, and again to oil of thyme. Examine on the slide under the low power of the microscope. If precipitates are present, or differentiation is insufficient, differentiate further by alternate immersions in 95 per cent alcohol and oil of thyme, five seconds each.

Wash in xylene, two changes, and mount in cedar oil on a slide.

By this method the leptotriches should be deeply stained and easily recognizable when occurring, as is usually the case, in masses. Isolated leptotriches will probably not be recognized by inexperienced observers. If no leptotriches are visible, other structures, such as fibrin, granules of mast cells, and chromatin, may possibly be mistaken for them by those who have never seen these microorganisms. When leptotriches are present in masses, however, their appearance is so characteristic and so different from any other structures in the tissues that they are easily identified.

PNEUMONIA, The Sabin Agglutination Test and the Polysaccharide Skin Test (Francis)
as Indices of Recovery in, Fox, W. W., Rosi, R., and Winters, W. L. *Am J. M. Sc.*
200: 649, 1940.

The authors conclude from their observations that the agglutinin test is a reliable index to the development of increased resistance to the pneumococcus in the course of pneumonia. It is such a simple test that it may be readily used as a control for sulfapyridine treatment. It rarely becomes positive before the eighth day of the disease; and since in complicated cases it is delayed until the twelfth to thirteenth day, it is particularly important that sulfapyridine be continued longer in such cases. Relapse and late septic complications may be prevented if this is done.

The Francis test is reliable in only 50 per cent of the cases (with the polysaccharide solutions used). The solutions of polysaccharide are available only for the more common types.

A change from negative to positive Francis test occurs on an average of two days before the agglutinin test becomes strongly positive. When this change is noted, it is probably safe to decrease the dosage of sulfapyridine, and to discontinue it two days later.

As concluded in a previous paper, recovery in pneumonia treated with sulfapyridine depends on three factors: an adequate early leucocytosis, an adequately maintained sulfapyridine blood level, and development of active immunity by the patient for the type of pneumococcus causing his pneumonia. The agglutinin test is a simple, inexpensive, rapid method for determining the development of active immunity.

INTOXICATION, Use of the Urine in the Chemical Test for, Haggard, H. W., Greenberg, L. A., and Miller, R. P. *J. A. M. A.* 115: 1680, 1940.

In the medicolegal diagnosis of intoxication the concentration of alcohol in the blood is frequently estimated indirectly from that found in the urine.

Unless special precautions are taken, serious errors may occasionally occur.

The ratio of the concentration of alcohol in blood to that of urine varies only slightly with the specific gravity of the urine; the ratio as determined is 1:1.3.

Absorption of alcohol from the bladder into the blood does not occur to a significant extent if the concentration found in the urine after drinking alcohol.

PREGNANDIOL EXCRETION, Diagnostic Value of, in Pregnancy Disorders, Cope, C. L. *Brit. M. J.* 2: 545, 1940.

Pregnanediol is a product of corpus luteum and placental metabolism. Its excretion in the urine is relatively easily measured in any biochemical laboratory. An attempt has been

made to assess the diagnostic value of pregnanediol excretion in abnormal pregnancy. Its complete absence is nearly always evidence of serious abnormality, suggesting in early pregnancy the death of the fetus. The significance of a low pregnanediol excretion still remains uncertain. A normal pregnanediol excretion is not evidence that abortion will not occur or that the fetus is still alive. Both chronic nephritis and toxemia of pregnancy may interfere with pregnanediol excretion. Deviations from the normal excretion in these conditions do not necessarily mean that the gestation is abnormal. Pregnanediol excretion seems assured of a place as a diagnostic aid in obstetric disorders.

BLOOD COAGULATION, Effect of Nicotinic Acid on, Calder, R. M., and Kerby, G. P.
Am. J. M. Sc. 200: 590, 1940.

Clinical experience in a significantly large group of patients with chronic brucellosis revealed that nicotinic acid possesses the property of promoting coagulation of the blood. These patients often develop subcutaneous hemorrhages after slight trauma, and their blood clots slowly, retraction is imperfect, and the yield of serum is low. All these defects were completely remedied by the administration of nicotinic acid.

These observations were extended to a small group of patients with other clinical states associated with bleeding, and the results were uniformly encouraging. Presumably, the hemorrhagic tendencies in all these patients rested on a toxic, infectious basis.

Experimental studies reported show that nicotinic acid does not duplicate the action of, nor can it be substituted for, any of the known factors involved in blood clotting (calcium, platelets, thromboplastic principle, prothrombin, or thrombin). However, when it is added in vitro to blood containing excessive amounts of antithrombin (heparinized blood or samples from dogs in peptone or anaphylactic shock), it does induce coagulation. That this effect is not due to nonspecific alteration of hydrogen-ion concentration was indicated by contrast of nicotinic acid with seven other acids, none of which was as active in this respect as was nicotinic acid.

The quantities of nicotinic acid employed in in vitro experiments were so enormous when compared with the doses used clinically, that it is not justifiable to assume that the mechanism of its effect in patients is necessarily a chemical neutralization of antithrombin. Though such an explanation is possible. Certainly, in view of the small doses effective in patients, the results cannot be attributed to a nonspecific acid effect. It would seem logical to conclude that nicotinic acid corrects a fundamental deficiency in the organism; or, by some pharmacodynamic action (e.g., stimulation of the liver), induces the formation either of more prothrombin or of less antithrombin.

Whatever the mechanism of its action may be, experience indicates that further trial of nicotinic acid in various hemorrhagic states is warranted.

PNEUMONIA, PNEUMOCOCCIC, Should Serum Be Used in Addition to Sulfapyridine?
Dowling, H. F., Abernethy, T. J., and Hartman, C. R. J. A. M. A. 115: 2125, 1940.

A series of cases of pneumonia caused by pneumococcus type I through type VIII have been alternated for treatment with sulfapyridine alone and with sulfapyridine plus specific antipneumococcus serum. The mortality rate was 12.5 per cent in the group receiving sulfapyridine alone, and 9.8 per cent in the group receiving serum plus sulfapyridine. If the type III cases are omitted, the corresponding figures are 9.2 and 4.5 per cent, respectively.

Serum seemed to be particularly valuable as an adjunct to sulfapyridine in patients over 40 years of age.

Crisis occurred more frequently and was more prompt in the patients receiving serum in addition to sulfapyridine.

It is suggested that serum and sulfapyridine both be given to patients over 40 years of age with pneumonia and to those who are in need of a prompt defervescence.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vnughan, 201 West Franklin Street, Richmond, Va.

The Methods of Ferment Investigation* (Section 1)

THE Methods of Ferment Investigation is intended to review our present knowledge of all ferment methods used in industry, biology, and medicine. The complete work will have about 3,500 pages and will contain 214 different articles written by 131 collaborators from various countries throughout the world. The book will be written entirely in German. Up to now only the first section of the book has appeared. A short introduction given by E. Bamann (Tübingen) and K. Myrbäck (Stockholm). The first subdivision deals with the substrates of ester-splitting ferments: substrates of the lipases by E. Bamann, natural glycerides by K. H. Bauer (Leipzig), acetylcholine by R. Ammon (Königsberg), substrates of the tannases by O. T. Schmidt (Heidelberg), chlorophyll by H. Fischer (München), phosphoric acid esters by E. Hackenthal and M. Kobel (Berlin), phosphatides by S. Belfanti, A. Ercoli, and M. Francioli (Milan), phosphoric acid by T. Posternak (Genf), and sulfuric acid esters by E. Hackenthal and M. Kobel. The second subdivision discusses the carbohydrates and glycosides: sugar by E. L. Hirst (Bristol) and S. Peat (Birmingham), isolation of natural heterosides by J. Rabate (Paris), synthetic glycosides by H. Elsner (Berlin), and thioglycosides by F. Wrede (Berlin).

Despite the obvious fact that most of the authors tried to condense their material as far as possible, nearly all articles are written rather clearly and contain an enormous amount of useful literature references. For the moment, it is a disadvantage that all these references, which are cited only by name and number in the individual articles, are combined into one bibliography which will be published as the last section of the whole work.

—Ernst Fischer.

The Methods of Ferment Investigation† (Sections 2, 3, 4)

THE three recently published sections of the "Methods of Enzyme Investigations" contain more than 60 different articles by a large number of collaborators from various countries. The subdivision about carbohydrates and glycosides, started in the first section, is continued now by articles by A. Purr (Prag) about glycolysis and starch, by H. Elsner (Berlin) and co-workers about galactogen, fructosans, and chitin. Glucosans and zytans, ascorbic acid, and related substances are discussed by E. L. Hirst (Bristol) and S. Peat (Birmingham), polyuronides by H. Bock (Karlsruhe), chondroitin sulfuric acid by T. Soda (Tokyo), the phosphorus-free derivatives of the carbohydrates by H. K. Baerenscheen and J. Pany (Wien), and the phosphorus-containing derivatives by R. Robinson and M. G. Macfarlane (London). The next subdivision is formed by a lengthy contribution of W. Klein (Freiburg) about the nucleic acids and their derivatives and by some shorter chapters about the proteins and their derivatives by A. Schäffner (Prag), E. Abderhalden (Halle), and F. Leuthard (Zürich). The amides are discussed in an especially interesting article by C. G. Holmberg (Lund), the thiols and disulfides by T. Bersin (Marburg), and finally the nucleoproteins, lipoproteins, and glycoproteins by St. J. V. Przylecki (Warsaw).

The third section is mainly devoted to the description of the modern methods in enzyme investigations. K. Felix (Frankfurt) describes the use of enzymatic investigation for the determination of the chemical structure of substances of high molecular weight, while T. W.

*Die Methoden der Fermentforschung. Edited by Eugen Bamann, M.D. and Karl Myrbäck, M.D. Section 1 with 172 pages and 2 figures. Georg Thieme, Leipzig, 1940.

†Die Methoden der Fermentforschung. Edited by Eugen Bamann, M.D. and Karl Myrbäck, M.D. Section 2 with 303 pages and 6 figures. Section 3 with 392 pages and 249 figures. Section 4 with 407 pages and 177 figures. Georg Thieme, Leipzig, 1940.

Astbury (Leeds) and J. C. Derksen (Eindhoven) contributes three excellent chapters about x-ray spectrographic methods and their results. G. Kortüm and M. Kortüm-Seiler (Tübingen) discuss absorption spectrum, Raman spectrum, and fluorescence. Heyrovsky's polarographic methods for electrical potentials are described by R. Brdička (Prag), the magnetic methods by E. Müller (Jena), determination of viscosity by R. Mohr (Freiburg), and the ultracentrifuge and diffusion methods by O. Lamm (Uppsala). Short chapters about dielectric, kryoscopic, and osmotic methods for molecular weight determination are contributed by S. Arrhenius (Uppsala), D. Krüger (Berlin), and G. V. Schulz (Freiburg). L. Köfler (Innsbruck) describes microdetermination of the melting point and sublimation methods.

The rest of the third section and the whole fourth section deals with the enzymatic reactions themselves. E. Brunius (Stockholm) describes the various nomographic methods, M. Steiner (Göttingen) the maintenance and testing of suitable conditions for enzymatic reactions, and J. Lehman (Goteburg) the redox potential. "The calculation of the free energy of biochemical reaction" by W. Franke (München) is well written and instructive. The various physical and physico-chemical methods are summarized in several short chapters by L. Heilmeyer (Jena), B. J. Krijgsman (Utrecht), P. Wulff (Frankfurt), D. Krüger (Berlin), and by K. Linderstrøm-Lang and H. Holter (København), while the manometric methods are treated in a longer chapter by F. Dickens (Newcastle). The next subdivision is devoted strictly to chemical methods, especially micro-analytic methods: alcohols, aldehydes, and acids by M. Steiner and O. Glemser (Göttingen); carbohydrates by H. K. Barrensechen and J. Pany (Wien); colorimetric determination of carbohydrates by G. Haugard (København); purino bases by J. E. Jorpes (Stockholm); titration of the carboxyl and of the amino groups by W. Grassmann and P. Stadler (Dresden), and the volumetric and manometric determination of amino acids by the same authors. A short résumé of the more biological methods is given by E. Werle (Düsseldorf), while K. Linderstrøm-Lang and H. Holter (København) discuss very carefully the new histochemical methods. The last part of the fourth section contains the first chapters of the subdivision dealing with the isolation and testing of various enzymes. The general methods for preparation of enzyme-containing solutions are written up by H. Kraut and A. Weischer (Dortmund), the special methods for enzymes of invertebrates by B. J. Krijgsman (Utrecht), and those of bacteria by H. C. Werkman and H. G. Wood (Ames, Iowa), up to now the only American co-workers. Methods for the concentration of enzyme preparations by evaporation are summarized by L. Vogel and P. Laverenz (München), and separation methods by means of freezing are described by J. Hartmann (München). The two final chapters are very interesting reports by H. M. Karström (Helsinki) about bacteria as material for enzymatic investigations.

Without doubt, these three sections of the "methods of enzyme investigations" contain an enormous amount of useful material for investigation in this and related fields. It is regrettable that due to the war conditions, some of the non-German authors were unable to read the proofs, since otherwise some apparent errors due to the translation of their original articles would have been eliminated.

—Ernst Fischer.

Bacteriology of Public Health*

DIFFERING from other bacteriology books in that it does not incorporate laboratory methods, this text presents facts of pathologic bacteriology from a public health viewpoint. This has the effect of permitting the student to become oriented without being confused by too much unnecessary information; it does not, however, mean that the matter is dealt with in a superficial manner. Indeed, the author is to be commended on carefully weeding out that which is extraneous. The emphasis throughout is on the bacteriology of disease rather than on bacteria which incidentally cause disease. Following a historical review, one finds chapters on drinking water and disease, on food idiosyncrasies, food poisoning, and food infections, and then a chapter devoted to each of the bacterial, virus, and protozoal diseases. The book, which is well written, includes a good bibliography and index.

PROGRESS

HEPARIN

JOHN H. FERGUSON, M.D., AND A. J. GLAZKO, PH.D., ANN ARBOR, MICH.

NATURE AND ORIGIN

THE discovery of heparin resulted from the finding of McLean¹ (1916), a pupil of Howell, that certain impure heart and liver phosphatides were inhibitory to blood coagulation. As the result of extensive investigations under the direction of Howell² (Johns Hopkins, Baltimore, 1916—), Best³ (Connaught Laboratories, Toronto, 1933—), Fischer⁴ (Carlsberg Foundation, Copenhagen, 1931—), Jorpes⁵ (Carolinian Institute, Stockholm, 1935—), the heparins have been separated from the phospholipids and identified as substituted polysaccharides belonging to the class of mucosaminopolysulfuric esters. The known molecular building stones are (1) hexuronic (? glyeauronic acid); (2) glucosamine, which is characteristic of the mucotins, just as galactosamine is typical of the chondroitins; (3) acetic acid (linked to the amino-N, in conformity with the rule that all amino sugars in nature are monoacetylated) (Furth and others, 1934); (4) several sulfuric acids (ester-linked to the hydroxyls of the hexuronic acid or hexosamine, or both). Many variations and fractionations are possible and purified natural products, including crystalline salts, differ in chemical details and in anticoagulant potency. According to the Toronto workers, there is a surprising similarity of the crystallization process for the various barium salts, and the varying potency does not parallel the sulfur content, as suggested by the Stockholm School. The simplest and most practical assay (Howell) defines a "unit" of heparin as the amount required to keep 1 c.c. of cat blood fluid for twenty-four hours at 0° C. The Toronto standard beef-lung heparin of Charles and Scott represents about 100 units per milligram. Potency and purity are not altogether synonymous when it comes to the question of toxic reactions.

Most tissues yield some heparin, but liver and lungs are the best sources in the majority of species. Holmgren and Wilander⁶ believe the origin to be in

the metachromatic granules, stainable with toluidine blue in the Ehrlich mast cells (tissue basophiles), which commonly cluster around the blood vessels in the tissues which are richest in heparin. The granules are depleted in peptone shock. The Toronto workers have also demonstrated a rise in blood heparin during serum anaphylaxis in dog experiments, and this rise, together with the associated incoagulability of the blood (but not the shock), could be prevented by excision of the liver, thus proving that the heparin comes from liver reserves.

BLOOD-CLOTTING MECHANISMS

Our experimentation⁶ (1934—) in the field of *blood coagulation* has led to the following conclusions as to the mechanisms involved: The fibrin of the clot is formed from the plasma protein, fibrinogen, through the agency of a coagulant, thrombin. The thrombin is first formed from an inactive precursor, prothrombin, which is also associated with the plasma globulins. Whether or not thrombin is an enzyme (fibrinogen denaturase, Wöhlisch,⁷ Fischer⁸) and prothrombin its zymogen (mother substance) is still unsettled. The coagulant is either a protein or very intimately associated with proteins throughout various phases of their colloidal behavior. Among enzyme analogies to thrombin may be mentioned the papainases. We have found a crystalline papain, kindly supplied by Dr. A. K. Balls, of the U. S. Department of Agriculture, clotted a prothrombin-free fibrinogen in twelve seconds, with lysis of the clot a few minutes later.

The conversion of prothrombin to thrombin requires certain activators, the chief one (we believe) being *thromboplastic enzyme*, a tryptase-like component of aqueous tissue extracts, which is also present, to some extent, in Berkefelded plasma and prothrombin made from it. Ionized calcium salts and phospholipid cephalin are essential cofactors. Much of our work has dealt with these thromboplastic agents.

The clotting reactions, especially in their time relations, are sensitive to physical conditions, including dilution, temperature, pH, salt content, "wetting" (lowering of surface tension), and other factors influencing colloidal stability. Specific inhibitors may be classified as (1) antiprothrombic (Howell) if they interfere with the first phase (conversion of prothrombin to thrombin), and (2) antithrombic if they affect the thrombin-fibrinogen interaction (second phase). "Immediate" antithrombins evince their full degree of inhibition at once. "Progressive" antithrombins, on the other hand, inactivate thrombin in a progressive manner, to which the term "thrombinolysis" is applicable, if it is demonstrably an enzymatic process. It is not convincingly proved that proteolytic phenomena in blood coagulation result in nonprotein nitrogen increase (as in ordinary protein digestion). Probably there is only a minor degradation and perhaps rearrangement of the significant protein complexes. The overt proteolytic enzyme, trypsin (e.g., Northrop and Kunitz's crystalline preparation) shows three actions, viz., (a) clot-aiding (thromboplastic), (b) thrombin-destroying (thrombinolytic), and (c) fibrin-dissolving (fibrinolytic). We have demonstrated parallel phenomena with aqueous tissue extracts (crude thromboplastins) and the first two, at least, can be shown with Berkefelded (i.e., cell- and platelet-free) plasma and serum and with the usual prothrombin

preparations. Clot retraction is absent or defective, and fibrinolysis is not seen in thromboplastin-poor plasmas and thrombins.

MODES OF ACTION OF HEPARIN

We have shown that heparin can inhibit the tryptic digestion of casein.⁸ It also retards the thrombin-destroying action of trypsin and of serum.⁹ In this, of course, it is antagonistic to progressive antithrombin, but the amounts of heparin needed are too large to convince us that this is more than a matter of theoretical interest.

In systems of purified clotting agents, heparin is practically devoid of antithrombic action, but the addition of a little plasma or serum results in the prompt appearance of a strong inhibition.¹⁰ Heparin *plus* a plasma cofactor (Howell's proantithrombin), therefore, forms an "immediate" antithrombin,¹¹ the actions of which are very similar to those of other immediate antithrombins, e.g., ferrocyanides (polyvalent anions). The plasma cofactor has not yet been defined, but we have definitely ruled out crystalline serum albumin.¹⁰

We have confirmed¹² another important action of heparin, namely, the antiprothrombic (Howell and Holt, 1918). Several recent authors deny the first phase action of heparin or postulate an essential cofactor on insufficient experimental grounds. The difficulty is due to their use of strong tissue thromboplastins which obscure the heparin effect. Our experiments¹³ clearly show that heparin has two distinct actions in the first phase of clotting. First, it retards the rate of prothrombin conversion to an extent which is inversely proportional to the amount of thromboplastin present. This fits in with thromboplastin studies¹⁴ and with the inhibitory effect of heparin on trypsin.⁸ It is concluded that heparin inhibits the enzyme factor in the thromboplastin and, if there is a small enough amount of enzyme, its prothrombin-activating function will be slow in consequence. Given an abundance of the thromboplastic enzyme, the retardation by heparin will be missed if it is not looked for in the first few minutes. Secondly, there is an effect on the amount (*effectiveness*) of the thrombin formed. This requires even more carefully chosen experimental conditions for its demonstration. With a strong prothrombin and small amounts of heparin, the alteration in final potency (thrombic) is negligible. But if the prothrombin is weak enough, an appreciable fraction is rendered ineffective and this can readily be demonstrated by suitable tests. Our recent fully-controlled tests demonstrate a first phase cofactor in crude plasma "albumin."¹³

A common basis for all heparin actions is suggested by Fischer's¹⁵ (1931) observation that it combines with proteins (and protamines, Chargaff¹⁶), thus altering their electrochemical and colloidal properties. Depending on the isoelectric points, this may apply alike to enzyme and substrate.

PRACTICAL APPLICATIONS OF HEPARIN

Clinical uses have increased with improvements in purification and consequent lessening of toxicity of heparin preparations. Howell tried out his best preparations in 1928 to 1930 and found them noninjurious to human beings. Mason¹⁷ and others, however, had very poor results with the commercial preparations. In 1935 to 1936 the Stockholm group⁵ (Sköld; Hedenius

and Wilander) used the purified preparations of Jorpes and Bergström with no untoward effects, and they have continued to recommend heparin for transfusion and thrombosis prevention. The Toronto group³ had been trying their numerous preparations on animals since 1932, and in 1937 Murray, Jaques, Perrett, and Best¹⁸ advocated the Charles and Scott product for human use in the prevention of thrombosis of veins following injury.

As with insulin, the purified drug is expensive, but it is now available from the Connaught Laboratories in reasonably priced 10 c.c. sterile ampoules, containing a stable saline solution, assaying 1,000 units per cubic centimeter. Orally, it is not effective. Subcutaneously, the action is prolonged (usually five to eight hours), but is uncertain in degree and there is danger of bleeding at the injection site. The route of choice, therefore, is the intravenous, with all the usual precautions. This is safe and the anticoagulant effect is optimal but somewhat transient (averaging sixty to ninety minutes). Repeated injections are less reliable and more uneconomical than the *continuous intravenous drip*, but even with this, there is likely to be much variation as to the effective dosage.²⁰ The Toronto workers³ have identified a heparinase which is said to be responsible for these variations. About 10 per cent is lost in the urine. It is best to keep the coagulation time at fifteen to twenty minutes (normal is five to seven minutes), and the heparinization must never be started until after the complete arrest of all hemorrhage. Postoperatively, the Toronto group¹⁸ wait for four to twenty-four hours, but the Scandinavians⁵ are somewhat less conservative (two to three hours; Crafoord). The duration of treatment must be dictated by experience, but is commonly one to two days. The onset of hemorrhage (of any degree) and of undue edema in cases with an overtaxed circulation calls for discontinuance of the treatment. Heparin does not soften clots but, as much by the preservation of the platelets and lessening of their agglutination as by its anticoagulant effects, it minimizes thrombus formation. When thrombi do occur, they absorb more readily and completely, with less danger of extension and of embolism. The protamine, *salmine-sulfuric acid*, is a physiologic antagonist to heparin both in vitro and in vivo.¹⁹ The action is quantitative¹⁶ and the protamine in excess is itself an anticoagulant. Being a foreign protein (split product), there is danger of allergy, but it could be tried in the event of dangerous hemorrhage in a heparinized patient.

The main field of clinical usefulness is in *prevention* of thrombosis and in lessening the dangers of embolism (Murray¹⁸). Vision has been restored in some cases of thrombosis of the central retinal vein, which, ordinarily, leads to almost certain blindness (Holmin and Ploman²¹). Besides cases of peripheral vessel, coronary, and cerebral thrombosis, there are reports on the use of heparin in endocarditis²² and in malaria.²³ The surgeon is especially interested in its use in traumatic and postoperative thrombosis. The prophylactic regime in these conditions has already been dealt with, but the necessity for choice of suitable cases may be re-emphasized.

Heparin is said to have revolutionized vascular surgery, including both anastomoses and operative removal of clots.¹⁸ The prospect of permanent patency of the sutured vessels is greatly increased. Good results have been reported in lessening the repetition of embolism in phlebitis cases.

Being poorly absorbed through serous membranes, heparin is suggested for use in the prevention of adhesions in serous cavities. Basic experimental work in this regard was performed in 1935 by Miki and Satani²⁴ (Kioto) on rabbits. The exposed omentum was scarified with dry gauze, and the abdominal cavity was filled with ordinary commercial heparin before closure. The results were gratifying. Lehman and Boys²⁵ (Charlottesville, Va., 1940) have confirmed these experiments and extended them to include animals (rabbits and dogs) in which sepsis was produced by cutting off the tip of the appendix. Forty per cent of these dogs died from peritonitis and 11 per cent had local abscesses. In 30 animals which had healed in six weeks, the adhesions were counted and dissected, and hemostasis was secured. In addition to controls, three types of solution were tried in the abdominal cavity. Saline gave poorest results on re-examination two weeks later. Ascitic fluid was little better than the controls. A definite lessening in the recurrence of adhesions was noted when the Toronto heparin was used. In 1936 Widerström and Wilander² (Stockholm) had shown excellent results with Jorpes' heparin in the prevention of pleural adhesions in rabbits after thoracoparacentesis and injection of iodine.

Heparin is also advocated for Hnas' *exchange transfusion* (blood washing) in uremias,⁵ especially reflex anurias, where the object is to dialyze off the non-protein nitrogen retention products from the blood. The older methods had an anastomosing loop of collodion tubing immersed in warm Ringer-Locke's solution. Later techniques called for the dialysis of successive amounts of blood, heparinized in vitro, with subsequent reinjection.

With regard to its use in ordinary transfusions,⁵ heparin ranks somewhere between the citrate and whole blood methods.²⁶ It is more costly, and there is some danger of incomplete inhibition of coagulation. Heparin is not a good preservative for stored blood. There is little, if any, effect on the recipient's blood as the heparin is quickly diluted down and soon inactivated by heparinase. It is said to be safe even when there has been severe hemorrhage (bleeding ulcers, for instance).

Another method is to heparinize the donor (Hedenius, 1936) with 1 mg. of heparin (100 units) per kilogram intravenously.⁵ No untoward reactions are experienced by donor or recipient. The donor must not risk injury for a couple of hours. It is easier to get sufficient blood without interference due to clotting in the vein. The technique may be simplified. Indeed, in emergencies, the whole procedure may be carried out entirely by means of a few sterile syringes.

As a *blood preservative* for biochemical and other purposes, heparin has advantages and disadvantages. It is anticomplementary. Many of its applications are still in the experimental stage and the scope of its clinical usefulness is especially a problem for the future to decide.

CLINICAL AND EXPERIMENTAL

EXPERIMENTAL STUDIES IN CARDIOVASCULAR PATHOLOGY*

II. PATHOLOGIC LESIONS IN ORGANS OF CATS, GUINEA PIGS, AND FROGS PRODUCED BY DIGITALIS POISONING

W. C. HUEPER, M.D., AND C. T. ICHNIOWSKI, PH.D., NEW YORK, N. Y.

RECENT investigations of Weese and Dieckhoff¹ on the one hand, and of Büchner² as well as Bauer and Fromherz³ on the other hand, have again raised the controversial question as to whether the toxic effects exerted by digitalis glycosides upon the functional activity of the heart muscle are caused by the storage and cumulation of these substances in these elements, as contended by Hatcher,⁴ or whether they are the result of myocardial lesions directly or indirectly produced by these glycosides and thus represent, after repeated administration of digitalis preparations, manifestations elicited by the superimposition of successive anatomic myocardial lesions produced by the individual doses of the digitalis glycosides administered. The conception of an additive anatomic effect as the cause of toxic symptoms from repeated digitalization is based upon the demonstration of hemorrhagic, degenerative, and necrotic myocardial lesions in the hearts of dogs, cats, rabbits, and frogs following the introduction of sublethal and lethal doses of various digitalis preparations (Lewitzki,⁵ Büchner,² Bauer and Reindel,⁶ Hu, Lien, and Li,⁷ Korth and Spang,⁸ and Lindner)⁹.

It is evident that a clarification of the action mechanism of digitalis glycosides, particularly in "cumulative" respects, is of utmost clinical importance since these drugs are used frequently over prolonged periods, until toxic symptoms become apparent. The clinical and pharmacologic observations cannot be correlated satisfactorily with the pathologic data available on this subject because the pathologic studies have been restricted to the heart. This organ was found to be without any myocardial lesions in some animals dying from subacute digitalis poisoning, and exhibited severe anatomic changes in other animals. An experimental reinvestigation of the pharmaco-pathologic interrelations of digitalis poisoning appeared to be indicated wherein special emphasis was to be placed upon a detailed pathologic study of all internal organs.

EXPERIMENTAL.

A purified digitalis preparation, representing the total activity of the leaf, was used in the experiments. Guinea pigs and cats received the drug by intramuscular injection, while frogs were subjected to administrations into the lymph sac. The study consisted of three sets of experiments. Eight guinea

pigs were injected with a single lethal dose of the digitalis preparation. Sixteen cats received intramuscular injections of one-fifth (10 cats) to one-tenth (6 cats) of the single lethal dose daily until death. Thirty-three frogs were injected daily with the solution of the purified digitalis preparation. The daily amount administered to the frogs was equivalent to one-tenth of the 50 per cent mortality dose for the first twenty-eight days of the experiment and was then increased to one-fifth of the dose for the following five days, after which the treatment was discontinued for the surviving 22 animals.

Series I. Single Lethal Dose.—Two of the 8 guinea pigs died within one to two days after the injection of the lethal dose of the digitalis preparation; 4 died after three to four days; 2 after six to ten days. Post-mortem findings: The lungs were congested and edematous, containing scattered hemorrhagic areas. The left ventricle was firmly contracted, appearing occasionally paler than the excessively dilated right ventricle. The subepicardial vessels were markedly hyperemic. The suprarenals were enlarged and congested and contained medullary hemorrhages in 3 animals. The internal organs, especially the liver, mesentery, intestine, and meninges, exhibited congested blood vessels.

Histology.—Heart: No myocardial abnormalities were found in the hearts of the 2 guinea pigs which died within the first forty-eight hours. One of them, however, showed several small subendocardial hemorrhages. The hearts of 3 of the 4 animals dying within forty-eight to ninety-six hours were free from degenerative myocardial lesions. Small leucocytic foci were present in the myocardium of the fourth animal, in which also a few scattered hyaline degenerated muscle cells were observed. Extensive and multiple areas of hyaline degeneration and necrosis often associated with leucocytic infiltrations were found in the hearts of the 2 guinea pigs which died six to ten days after the injection. Several necrotic foci showed calcium incrustations. There were subepicardial hemorrhages in both animals and subendocardial hemorrhages in one.

Lung: Venous congestion, pulmonary edema, and intra-alveolar hemorrhages were present in all animals.

Liver: Congestion of the hepatic vessels was especially marked in the peripheral zones, where hemorrhages were found occasionally. Multiple, large hyaline necroses existed in the liver of the guinea pig which survived for ten days.

Suprarenal Glands: In addition to the marked congestion and edema present in every case, there existed a hemorrhagic destruction of the medulla in the suprarenal glands of 3 guinea pigs.

Testes: A moderate degeneration of the spermatogenic epithelium was found in 3 animals.

Brain: Only the brain of the guinea pig which died on the sixth day was studied. The meningeal and cerebral vessels were congested markedly, and the cerebral parenchyma was edematous. Small hemorrhages were observed in the region of the floor of the fourth ventricle, where also vacuolated and disintegrating swollen ganglion cells were noted scattered in several centers.

The other organs were normal with the exception of varying degrees of hyperemia.

Series II. Repeated Sublethal Doses.—Symptomatic Observations: The cats reacted after the first injection of the digitalis glycosides with increased salivation, nausea, emesis, and signs of general discomfort, rarely assuming the degree of retching movements or marked general distress. These symptoms disappeared in general within the first twenty-four hours, when loss of appetite, drowsiness, and apathy set in and continued in most animals until death occurred. New attacks of vomiting, accompanied sometimes by diarrhea, were seen, however, in a few cats following repeated injections. Spastic convulsions did not occur. It was noted that the heart action became progressively rapid and irregular during the course of the experiment, so that a "racing heart" and signs of heart block existed in most animals for some time before death. Of the 6 cats which received daily one-tenth of the single lethal dose, one died after four injections, one after seven injections, and 4 after ten to twelve injections. Of the 10 cats composing the group receiving daily one-fifth of the single lethal dose, 6 died after three to five injections, 3 survived six to eight injections, and one died after fifteen injections.

Pathologic Observations.—The post-mortem examinations showed that the hearts had a hard and firmly contracted left ventricle, while the right side of the heart, and especially the right auricle, were dilated. The subepicardial veins were engorged, whereas the coronary epicardial arteries were collapsed and appeared as white strands between the swollen and projecting accompanying veins. Small dark red hemorrhagic areas in the subepicardial tissue were found in one heart near the circular sulcus. A serohemorrhagic pericardial fluid was observed in 3 cats. The lungs were congested and sometimes contained small scattered hemorrhagic areas. The other internal organs were without any appreciable pathologic changes. The meningeal vessels were hyperemic.

Histology.—Heart: Marked pathologic changes were present in the left ventricular wall, the interventricular septum, and especially in the papillary muscle of the left ventricle of the hearts of the 5 cats which died three to five days after the start of the experiment. The lesions were located mainly in the subendocardial region and near the apex. The right ventricular wall as well as the walls of the auricles exhibited only occasionally myocardial changes. There were areas composed of swollen and hydropic muscle cells revealing a rarefaction of the sarcous content (Fig. 1). In other parts there was a more or less marked interstitial edema, proliferation of histiocytes and of fibroblasts present replacing degenerated muscle cells. Multiple foci contained fragmented, partly hyalinized or rarefied muscle cells showing not infrequently a tortuous shape or having cross bands of sarcous granular densifications (contraction bands) (Fig. 2). Scattered calcifications were found in smaller lesions of coagulation necrosis. Hemorrhagic lesions containing muscular fragments in a state of granular or lytic disintegration and infiltrated with leucocytes and lymphocytes were repeatedly seen in the subendocardial zone (Fig. 3). There was an edematous swelling of several medium-sized arterioles (Fig. 4). The subepicardial and myocardial coronary arteries were firmly contracted, while the veins were dilated and engorged. Capillaries located within the degenerated and necrotic areas sometimes showed swollen and thickened walls lined with a proliferated endothelium.

In contrast to these very extensive and severe myocardial lesions present in these 5 cats, the tissues exhibited only minor changes in 2 additional cats dying after three to five injections. Similarly, there were only marked hemorrhagic, degenerative, and necrotic tissue reactions found in the hearts of 2 of the

Fig. 2.—Fragmentation and hyaline and vacuolar degeneration of the myocardial cells with interstitial edema and leucocytic infiltration.

Fig. 3.—Subendocardial necrosis and hemorrhage with marked leucocytic infiltration into the edematous tissue containing partially lysed muscle cells.

Fig. 4.—Myocardial arteriole with swollen and edematous wall.

9 cats which died after six to fifteen injections, while the hearts of the other 7 animals exhibited only scanty and mild degenerative lesions. Numerous small fibroblastic scars, in addition to extensive regressive and inflammatory myocardial lesions, were observed in the heart of the cat which died after fifteen injections.

(Glycogen stains of the heart sections made with the Best's carmine method were negative in four instances and showed mere traces in a fifth case.

Lung: The veins were markedly engorged, the arteries were collapsed, and the pulmonary parenchyma showed intra-alveolar edema and scattered hemorrhages.

Fig. 5.—Degenerated ganglion cells and neuronophagia in a center located at the floor of the fourth ventricle.

Liver: In addition to marked, especially pericentral congestion, there existed interstitial edema and hemorrhages accompanied by hepatic atrophy in several cases. Glycogen stains were negative.

The other internal organs (kidney, spleen, suprarenals, pancreas, lymph nodes, intestine, stomach, ovary, bone marrow, uterus, etc.) showed varying degrees of congestion.

Brain: There were degenerative glial and ganglionic cellular changes present in the majority of cats. These lesions were remarkable, particularly in some of the cats which died with minor myocardial degenerative manifestations. The lesions consisted of vacuolization and disintegration of individual ganglion cells located in the centers of the basal region and in the brain stem (Fig. 5). In two instances smaller glial cell infiltrations were found in the cerebellum (Fig. 6), while markedly engorged capillaries with focal degeneration of the nervous substance were seen occasionally (Fig. 7).

Series III. Prolonged Repeated Injections.—Five frogs lived for four to six days, 4 for ten to twenty days, 2 for twenty-nine to thirty-one days, 16 for forty to forty-three days, and 6 for seventy to seventy-five days. All frogs which survived for more than forty-two days were killed. The hearts of the majority of the frogs which died spontaneously showed a firmly contracted grayish red

Fig. 6.—Glial focus in the cerebellum.

Fig. 7.—Congested capillaries surrounding a focus of degenerated nervous substance.

to pale yellowish-gray ventricle, which seemed to be attached like a small nodule to the markedly distended and engorged auricle. The lungs of these animals were often congested. The stomach was distended and contained a thick jellylike grayish white matter. The organs of the animals which were sacrificed after the arrest of the treatment exhibited normal organs.

Fig. 8.—Contraction bands in the heart of a frog.

Histology.—Heart: The most characteristic and frequent, while by no means constant abnormality found in the hearts of the frogs which died during treatment was a marked swelling and hydropic condition of the muscle cells of the ventricle. Contraction bands consisting of hyaline, granular material, which was indistinctly demarcated from the adjacent hydropic sarcolemmal content of the cells, were running crosswise to the longitudinal axis of muscle bundles (Fig. 8). Because of the firm contraction of the ventricle very little blood was present in between the nonvascularized muscular trabeculae composing the wall of the frog heart. There were no degenerative lesions.

The liver and kidney were congested and often edematous.

The internal organs of the frogs killed after cessation of the treatment were normal.

COMMENT

The pathologic observations made regarding the presence and type of myocardial lesions found in animals dying from digitalis poisoning confirm in general those previously recorded. They substantiate, moreover, the statements of Bauer and Reindell,⁶ and Lindner,² that such anatomic myocardial changes are not present in all animals (in 80 per cent, according to Bauer and Reindell) subjected to lethal and sublethal doses of digitalis glycosides. It is obvious, therefore, that myocardial pathology cannot represent in all instances the cause of symptomatic toxic manifestations observed during life and its lethal sequelae, as contended by Büchner,² and Bauer and Fromherz.³ In addition to these

cases in which no appreciable myocardial lesions exist, there are others in which the anatomic changes in the heart after toxic doses of digitalis glycosides are so mild that they cannot be considered as a major etiologic factor in bringing about the lethal results observed. While these considerations seem to discredit the anatomic conceptions of Büchner, and Bauer and Fromherz, and support apparently the functional-cumulative theory of Hatcher,⁴ there remains the possibility that primary or secondary extracardiac organic anatomic lesions, such as described in this presentation, may be involved in or contribute to the causation of the toxic symptomatic reactions, particularly those affecting the heart and the nervous system, and of the fatal end results.

There exists a certain amount of functional and anatomic evidence indicating that such a causative mechanism may play a part in the appearance of the toxic and fatal manifestations associated with digitalis poisoning in animals. It is a well-recognized fact that an overdigitalization leads to an excessively prolonged and accentuated systolic contraction and an incomplete and shortened diastolic dilation of the ventricles. This functional state of the myocardium results in a more or less serious circulatory impairment characterized by a defective filling of the arterial system and a retention of the blood in the venous system. Such a circulatory state produces a relative stagnant hypoxemia in the extracardiac organs followed, when prolonged, by the development of degenerative changes in those organs, such as the brain, which are particularly sensitive to deficiencies in their oxygen supply. This hypoxemic condition is accentuated during attacks of vomiting and convulsions, and during the state of the racing heart, which in turn aggravate the ischemic anoxemia of the myocardium resulting from the compression of the myocardial arterioles by the bulges of the contracted muscle bundles (Anrep,¹⁰ Fock¹¹) and interfering with the functional efficacy of the myocardium. Thus, a vicious circle is established between disturbances of the functional activity of the heart with its resulting circulatory effects and the functional and anatomic changes elicited by these conditions in extracardiac organs. The site (suprarenal, brain) and character of these lesions (hemorrhages, degeneration of ganglion cells in the region of vitally important centers) as well as their potentially progressive nature suggest that they may be the cause not only of prolonged functional cardiac disturbances, but also of the occurrence of the delayed deaths observed in animals without appreciable or severe myocardial pathology.

In view of the complete absence of corresponding observations in connection with the toxic reactions associated with a therapeutic overdigitalization in man, it remains uncertain whether a similar vicious circle of functional and anatomic reactions is produced and may contribute to the untoward effects noted sometimes in patients subjected to this type of treatment.

CONCLUSIONS

The introduction of single lethal doses of digitalis glycosides into guinea pigs, as well as of repeated sublethal doses of the drug into cats, results in the production of degenerative and necrotic myocardial and extracardiac (cerebral, suprarenal, hepatic, renal) organic lesions in the majority of the animals treated.

Some of the animals, however, dying from the toxic effects of the digitalis glycosides show at death no appreciable, or only minor cardiac, changes, while the extracardiac, and particularly cerebral, lesions are well developed.

The anatomic evidence obtained indicates that subacute and delayed death from digitalis poisoning may be the result of anatomic, myocardial lesions of severe type or, in the absence of these, of extracardiac cerebral or suprarenal lesions.

FURTHER STUDIES ON THE BEHAVIOR OF GLUCONIC ACID AND AMMONIUM GLUCONATE IN ANIMALS AND MAN*

MAYNARD B. CHENOWETH, A.B., HELEN CIVIN, M.S., CHARLES SALZMAN, B.S.,
MILTON COHN, M.D., AND HARRY GOLD, M.D., NEW YORK, N. Y.

THE present report deals with a study of certain aspects of the pharmacology of gluconic acid, in particular its effect on the pH of the urine, its excretion in the urine, and its toxicity by oral and intravenous injection in acute and chronic experiments.

Mechanism of Increased Urinary Acidity After Gluconic Acid.—In a previous study¹ we found that large oral doses of gluconic acid† administered to human subjects sometimes increased the acidity of the urine, the pH falling from 0.1 to 1.0 unit. Such a decline in the pH need not necessarily be due to excreted gluconic acid, since the administration of an organic acid which shifts the acid-base equilibrium of the blood toward the acid side may result in increased

*From the Department of Pharmacology, Cornell University Medical College, New York.
Received for publication, June 7, 1940.

†Throughout these studies the preparation used was glucono-delta-lactone of Charles Pfizer & Co., Inc.

These studies were aided by a grant from Charles Pfizer & Co., Inc.

excretion of acid phosphates, and this factor may be responsible for the shift in the pH of the urine. We pointed out in the previous study that the fate of gluconic acid is not established, some studies indicating a high degree of excretion and others the possibility that it is chiefly destroyed. We, therefore, performed experiments to ascertain the role of excreted gluconic acid in producing the changes in the pH of the urine.

In the first group of experiments gluconic acid was added to urine of 6 normal subjects and of one with a urinary infection, in concentrations varying from 0.1 to 5 per cent gluconic acid. Forty-three pH determinations were made. The results showed a fall in the pH of from 0.1 to 1.2 units. All pH determinations were made with the Leeds and Northrup potentiometer using the glass electrode. In general, the higher the concentration of gluconic acid, the greater the decrease in the pH of the urine. Marked variations were in evidence, however, among different specimens of urine. For example, in each of two urines, in which the pH decreased by 0.6, the change was brought about by a 0.9 per cent solution of gluconic acid in the one and by a 5 per cent solution in the other. A 1 per cent solution of gluconic acid lowered the pH by as little as 0.1 in one urine, while the same change of pH was produced by a much more dilute solution of gluconic acid, 0.2 per cent, in another specimen. The original pH is not the sole factor that determines these variations, since two urines having the same pH at the start may show quite different changes with the same concentrations of gluconic acid. For example, in the case of two urines each of which had a pH of 5.9, one showed a decrease of 0.9 and the other a decrease of 0.6 with a gluconic acid concentration of 2.5 per cent; similarly, when the concentration of gluconic acid was raised to 5 per cent in these two, the pH decreased by 1.2 in one and by 0.9 in the other. These differences, as might be expected, are due to the different buffering powers of various urines.

These experiments showed that the gluconic acid content of urine after large oral doses in man should be 0.3 per cent or higher in order to produce an appreciable fall in the pH of the urine, such as, for example, 0.1 to 0.3 unit.

Gluconic acid is much less effective than mandelic acid in lowering the pH. In one specimen of urine a 5 per cent solution of gluconic acid produced a smaller effect (fall of pH by 1.2) than a 1 per cent solution of mandelic acid (fall of pH by 2.5).

GLUCONIC ACID EXCRETION IN URINE AFTER ORAL ADMINISTRATION

Experiments were then performed to determine the gluconic acid content of urine in human subjects after the oral administration of large doses.

An attempt was first made to determine the gluconic acid by the preparation of its phenylhydrazide, according to the technique described by Fischer and Passmore,² and modified by Kiliani³ and Van Marle.⁴

In one experiment in which 200 mg. of gluconic acid were added to 25 c.c. of distilled water, a yield of 98 per cent of the theoretical quantity of the phenylhydrazide was obtained. It gave the melting point of gluconic acid phenylhydrazide, namely, 200° C. Each of two specimens of urine was divided into four 25 c.c. portions, and gluconic acid was added in amounts varying from 200

to 400 mg. The yield varied from 10 to 69 per cent of the added gluconic acid for the 8 samples, and from 18 to 69 per cent for the samples of the same specimen.

An attempt was made to recover gluconic acid phenylhydrazide from the urine collected three hours after the oral administration of 5 to 20 Gm. of gluconic acid in 5 persons. None was recovered in 3. In 2 others the recoveries were 10 and 160 mg., respectively. The crystals were impure. These results showed that the phenylhydrazide method applied to urine yields hydrazides other than that of gluconic acid and is not a satisfactory method for determining the excretion of gluconic acid in urine. As far as the results go, however, they indicate that very little of a large oral dose of gluconic acid is excreted in the urine in man.

In another series of experiments an attempt was made to determine the urinary excretion of gluconic acid polarimetrically by means of the alkaline molybdate complex. De Carli⁵ showed that the specific rotation of gluconic acid is very low. However, Lütz and Jirgensons,⁶ and Schmidt and Weber-Molster⁷ showed that the specific rotation of various aldonic acids can be greatly increased by forming complexes with sodium or ammonium molybdate. Bennet-Clark⁸ employed acid solutions of ammonium molybdate for determining gluconic acid in plant extracts. The acid solution, however, is not applicable to urine because of other substances normally present which color the molybdate, and Lütz and Jirgensons⁶ showed that the greatest rotation in the case of gluconic acid is obtained in alkaline solution.

The urine was first cleared by centrifuging twice at 4,000 r.p.m. It was decanted into a fine filter and allowed to filter slowly in the refrigerator. Charcoal or other similar agents for clearing urine are undesirable in the case of gluconic acid.⁹ Eight cubic centimeters of the clarified urine were placed in a 50 c.c. Erlenmeyer flask. To this 5 c.c. of a saturated aqueous solution of ammonium molybdate were added, and 0.5 c.c. of 24 per cent sodium hydroxide. This was made up to 25 c.c. with distilled water. It was well mixed and allowed to stand in the dark for about one hour, although the indications are that accurate readings can be made in from thirty minutes to twenty-four hours. A determination

TABLE I

EFFECT OF THE CONCENTRATION OF GLUCONIC ACID ON THE DEGREE OF OPTICAL ROTATION IN URINE

CONCENTRATION OF GLUCONIC ACID LACTONE (%)	ANGLE OF ROTATION
2.0	3.49
1.5	2.55
1.0	1.66
0.9	1.47
0.8	1.30
0.7	1.15
0.6	0.97
0.5	0.80
0.4	0.64
0.3	0.46
0.2	0.32
0.1	0.17

Distilled water	0.00

of the relationship between the concentration of gluconic acid lactone in urine and the angle of rotation showed that with concentrations between 0.1 and 2.0 per cent this relationship is a straight line function (Table I).

The polarimetric method of determining gluconic acid in urine was applied to four experiments in a dog and to thirty experiments in six persons. Illustrative data are presented in Table II. A normal female dog was placed in a metabolism cage and kept on a normal stock diet with unlimited water. The bladder was emptied before the drug was administered. Urine specimens were collected from the bladder by means of a catheter at intervals of from one-half to seven and a half hours after the dose. To insure a satisfactory volume of urine, 100 c.c. of tap water were placed in the stomach after the doses of the drug in three of the four experiments. Each experiment was done on a different day. The following doses were used: 0.5 Gm. of gluconic acid per kilogram intravenously in two experiments, 1 Gm. per kilogram by stomach tube in the third, and 1.5 Gm. per kilogram by stomach tube in the fourth. The pH of the urine specimens collected from one-half to five hours after the dose was usually less than 5.5, and ranged from 4.8 to 6.0. The results showed that the dog excretes some gluconic acid in the urine, more after intravenous injections than after oral administration. In the case of the intravenous injections, most of the excretion took place in the first half hour. The total amount excreted in the urine in either case was small, namely, 1.1 and 2.4 per cent of

*Both oral and intravenous doses were given as a 10 per cent solution of the delta lactone of gluconic acid.

†These time intervals represent the period from the administration of the drug to the collection of the sample of urine.

preciable sustained injury is equivalent to an intravenous injection of 30 Gm. for the average man on the basis of body weight. It is clear, therefore, that the toxicity of ammonium gluconate or gluconic acid by intravenous injection is very low.

Effect of Gluconic Acid on the Urine of Human Subjects.—The urines of 5 normal persons were examined for protein, casts, blood cells, pus cells, and sugar. The subjects were then given daily doses of gluconic acid of 5 to 10 Gm. each for periods varying from three to six days. At the end of this period the urine was re-examined in the same way. The results show that gluconic acid produces no signs of renal injury, judged in this way.

Effect of Gluconic Acid on the pH of the Urine.—In the previous study¹ the results of experiments were presented showing that the delta lactone of gluconic acid given in large doses reduced to low levels the pH of the urine in normal human subjects. The dose was 15 Gm. of gluconic acid given orally on an empty stomach. The bladder was emptied at the time the dose was taken, and the urine secreted during the first four-hour period after the dose was examined for the pH. Inasmuch as the larger doses had a fairly marked tendency to cause cramps and diarrhea, similar experiments were now made with 5 Gm. doses in order to see whether changes in the pH of the urine could be produced without the gastrointestinal symptoms. These experiments were carried out in 10 persons, 5 with and 5 without a urinary infection. Control specimens of urine were examined for the pH under the same conditions as those after the dose of the drug. In the different patients the average pH for the controls was based upon the results in from five to sixteen specimens, and after the gluconic acid the average pH was based upon the results in from five to thirty-seven specimens. The results with the 5 Gm. doses were equivocal. The doses were then increased to from 10 to 50 Gm. given at one time. Marked variations in the changes of the average pH of the urine after the drug were observed. In the different cases they were as follows: +0.9, -0.2, +0.4, +0.1, -0.3, -0.5, 0.0, -0.7, -0.1, and -0.9. Urinary infection was present in the first five of these cases. It appears, therefore, that normal and infected urines do not behave alike. In normal urine the pH usually declined. In infected urine a decline rarely occurred. In fact, the usual response was a rise of the pH. A similar resistance of infected urine to acidification by intravenous injections of gluconic acid in human beings was reported by Bodon.¹⁰

Effect of Ammonium Gluconate.—In a group of 8 persons the effect of ammonium gluconate on the pH of the urine was tested. There were 2 with infected urine and 6 with normal urine. The experiments were carried out in a manner similar to those in which the delta lactone of gluconic acid was used. The doses were from 5 to 30 Gm., given in the form of a powder, dissolved in 8 ounces of water, with the urinary bladder empty, four hours before the specimen of urine was collected. The results showed that ammonium gluconate in such doses as these also tends to reduce the pH of normal urine, and in the two subjects with infected urine, the pH did not fall, but rose. Four of the 8 patients developed nausea, cramps, and diarrhea. These disagreeable effects of ammonium gluconate, therefore, are similar to those encountered during the use of gluconic acid.

Illustrative data of the effect of gluconic acid and ammonium gluconate on the pH of the urine in man are presented in Table III.

SUMMARY AND CONCLUSIONS

1. A method has been developed for the determination of gluconic acid in urine polarimetrically by means of the ammonium molybdate complex of gluconic acid.
2. It has been determined that the degree of optical rotation produced by the complex of gluconic acid bears a straight line relationship to the concentration of gluconic acid.
3. After large oral doses of gluconic acid the urine, when treated with ammonium molybdate, develops optical rotation. We have assumed it to represent excreted gluconic acid.
4. After 10 to 30 Gm. doses of gluconic acid given orally, human subjects were found to excrete an amount varying from 7.7 to 15.0 per cent of the dose in the succeeding twenty-four hours, the major part of the excretion taking place within the first few hours.
5. After doses of 10 to 30 Gm. of gluconic acid the concentration in the urine is extremely variable, ranging from 0.03 to 2.24 per cent, usually, however, less than 0.5 per cent.
6. In vitro experiments in which gluconic acid was added to the urine showed that the foregoing concentrations could account for the amount of decrease of the pH of the urine which followed the oral doses of gluconic acid. It is inferred, therefore, that the fall of the urinary pH after the administration of gluconic acid is due to the excreted gluconic acid, or some closely allied acid derivative.

1.0 to 1.5 Gm. per kilogram by oral administration, and 5.4 and 6.0 per cent of 0.5 Gm. per kilogram by intravenous injection.

In the human subjects the gluconic acid was given in a single dose of 5, 10, 20, or 30 Gm. orally at 9 A.M., after a constant breakfast at about 8 A.M. The bladder was emptied just before the drug was taken dissolved in 8 ounces of water. No food was taken until after the first sample of urine which was collected, three and a half hours following the drug. The second sample was collected seven hours after the drug, and the third sample represented the pooled urine voided up to twenty-four hours after the drug. Variable amounts of gluconic acid appeared in the urine after its oral administration. None was recovered after a 5 Gm. dose in two experiments. After from 10 to 30 Gm. doses, 0.5 to 17.5 per cent appeared in the urine. The recovery varied greatly in the same individual after a similar dose and similar interval on different days. For example, in one subject who received a 10 Gm. dose on each of five days, the recovery of gluconic acid in the urine three and a half hours after each dose varied as follows: 1.4, 2.2, 2.6, 0.0, 5.7 per cent of the dose. The largest amount usually appeared in the first seven hours after the ingestion. In four experiments in which the total excretion was determined, it varied from 7.7 to 15 per cent of the 10 Gm. dose.

The concentration of gluconic acid in the urine of the dog varied from 0.01 to 4.4 per cent. In human subjects in whom the doses were smaller on the basis of body weight, the concentrations ranged from 0.03 to 2.24 per cent.

The decrease in the pH of the urine after gluconic acid in oral doses of from 5 to 50 Gm. ranged from 0.1 to 1.0. When gluconic acid was added to urine, it was found that concentrations of from 0.1 to 0.9 per cent produced decreases in the pH of the order of 0.1 to 0.6 unit. Since such concentrations of gluconic acid appear in the urine after oral doses, we may conclude that the pH of the urine following the oral administration of gluconic acid could be explained by the excreted gluconic acid as estimated above.

We have observed that control urine does not form an optically active complex with ammonium molybdate in the manner in which these experiments were performed. Furthermore, the urine secreted after the injection of gluconic acid is not optically active until its ammonium molybdate complex has been formed. We have assumed that this optically active compound represents gluconic acid, the amount of which was calculated in terms of the lactone. The possibility that this compound which appears may not be gluconic acid, but some related conversion product which possesses little direct optical activity, but which develops optical rotation as its ammonium molybdate complex in a manner similar to gluconic acid, has not been excluded.

TOXICITY OF GLUCONIC ACID

In the Cat and the Dog.—Each of 5 cats received a daily dose of 1 Gm. of gluconic acid per kilogram as a 10 per cent solution by stomach tube for fourteen days. Daily observations were made for signs of toxicity, and the urine was examined daily for protein, blood, casts, and sugar. The urine was also examined during a control period of five days prior to the administration of the

drug. The animals were weighed at the beginning and again at the end of the experimental period.

The general appearance of the animals remained unchanged. They retained their control weight. Three developed vomiting and diarrhea on several occasions. The urine remained unchanged.

At the end of the two weeks the animals were killed with ether or chloroform, and on gross examination the lungs, heart, liver, kidneys, gastrointestinal tract, bladder, ureter, and spleen were found normal. Sections of the lungs, liver, and kidneys were prepared, stained with hematoxylin and eosin, and examined histologically. In all there were 126 such sections. These also failed to show any significant changes when compared with the tissues of 2 normal cats examined in the same way.

Fig. 1.

A similar series of experiments was carried out on 3 dogs. The results are similar to those obtained in the cats. No signs of ill health developed during the period of two weeks. The urine remained unchanged and at autopsy no significant gross or histologic changes in the tissues (33 sections examined) were found.

Effect of Intravenous Injection in the Cat.—Fig. 1 shows the effect of gluconic acid and ammonium gluconate given by intravenous injection in the cat. A dose of 500 mg. per kilogram produced a temporary fall of the blood pressure, which returned to the normal level within about five minutes. Eight minutes later a similar dose of ammonium gluconate was given. This also produced a temporary fall of the blood pressure, followed by a marked secondary rise. An additional dose of 275 mg. per kilogram given very rapidly about twenty minutes later produced abrupt cessation of the heart. The dose which produced no ap-

preciable sustained injury is equivalent to an intravenous injection of 30 Gm. for the average man on the basis of body weight. It is clear, therefore, that the toxicity of ammonium gluconate or gluconic acid by intravenous injection is very low.

Effect of Gluconic Acid on the Urine of Human Subjects.—The urines of 5 normal persons were examined for protein, casts, blood cells, pus cells, and sugar. The subjects were then given daily doses of gluconic acid of 5 to 10 Gm. each for periods varying from three to six days. At the end of this period the urine was re-examined in the same way. The results show that gluconic acid produces no signs of renal injury, judged in this way.

Effect of Gluconic Acid on the pH of the Urine.—In the previous study¹ the results of experiments were presented showing that the delta lactone of gluconic acid given in large doses reduced to low levels the pH of the urine in normal human subjects. The dose was 15 Gm. of gluconic acid given orally on an empty stomach. The bladder was emptied at the time the dose was taken, and the urine secreted during the first four-hour period after the dose was examined for the pH. Inasmuch as the larger doses had a fairly marked tendency to cause cramps and diarrhea, similar experiments were now made with 5 Gm. doses in order to see whether changes in the pH of the urine could be produced without the gastrointestinal symptoms. These experiments were carried out in 10 persons, 5 with and 5 without a urinary infection. Control specimens of urine were examined for the pH under the same conditions as those after the dose of the drug. In the different patients the average pH for the controls was based upon the results in from five to sixteen specimens, and after the gluconic acid the average pH was based upon the results in from five to thirty-seven specimens. The results with the 5 Gm. doses were equivocal. The doses were then increased to from 10 to 50 Gm. given at one time. Marked variations in the changes of the average pH of the urine after the drug were observed. In the different cases they were as follows: +0.9, -0.2, +0.4, +0.1, -0.3, -0.5, 0.0, -0.7, -0.1, and -0.9. Urinary infection was present in the first five of these cases. It appears, therefore, that normal and infected urines do not behave alike. In normal urine the pH usually declined. In infected urine a decline rarely occurred. In fact, the usual response was a rise of the pH. A similar resistance of infected urine to acidification by intravenous injections of gluconic acid in human beings was reported by Bodon.¹⁰

Effect of Ammonium Gluconate.—In a group of 8 persons the effect of ammonium gluconate on the pH of the urine was tested. There were 2 with infected urine and 6 with normal urine. The experiments were carried out in a manner similar to those in which the delta lactone of gluconic acid was used. The doses were from 5 to 30 Gm., given in the form of a powder, dissolved in 8 ounces of water, with the urinary bladder empty, four hours before the specimen of urine was collected. The results showed that ammonium gluconate in such doses as these also tends to reduce the pH of normal urine, and in the two subjects with infected urine, the pH did not fall, but rose. Four of the 8 patients developed nausea, cramps, and diarrhea. These disagreeable effects of ammonium gluconate, therefore, are similar to those encountered during the use of gluconic acid.

Illustrative data of the effect of gluconic acid and ammonium gluconate on the pH of the urine in man are presented in Table III.

SUMMARY AND CONCLUSIONS

1. A method has been developed for the determination of gluconic acid in urine polarimetrically by means of the ammonium molybdate complex of gluconic acid.

2. It has been determined that the degree of optical rotation produced by the complex of gluconic acid bears a straight line relationship to the concentration of gluconic acid.

3. After large oral doses of gluconic acid the urine, when treated with ammonium molybdate, develops optical rotation. We have assumed it to represent excreted gluconic acid.

4. After 10 to 30 Gm. doses of gluconic acid given orally, human subjects were found to excrete an amount varying from 7.7 to 15.0 per cent of the dose in the succeeding twenty-four hours, the major part of the excretion taking place within the first few hours.

5. After doses of 10 to 30 Gm. of gluconic acid the concentration in the urine is extremely variable, ranging from 0.03 to 2.24 per cent, usually, however, less than 0.5 per cent.

6. In vitro experiments in which gluconic acid was added to the urine showed that the foregoing concentrations could account for the amount of decrease of the pH of the urine which followed the oral doses of gluconic acid. It is inferred, therefore, that the fall of the urinary pH after the administration of gluconic acid is due to the excreted gluconic acid, or some closely allied acid derivative.

7. Additional experiments with oral doses of gluconic acid confirm the previous results showing that the pH of the urine can be significantly reduced by doses of the order of 10 Gm. or more. Smaller doses produce equivocal results.

8. In a series of similar experiments with ammonium gluconate the pH of the urine was similarly lowered by similar doses.

9. While a significant lowering of the pH occurred almost uniformly in cases of normal urine, the reverse occurred in cases with urinary infections. In the latter the pH rarely fell and usually rose. The reason for this difference requires further study.

10. The acute toxicity of gluconic acid and ammonium gluconate is low. Only temporary fluctuations in the blood pressure are produced by an intravenous injection of a 10 per cent solution of gluconic acid or of ammonium gluconate in a dose of 0.5 Gm. per kilogram, equivalent to a total of about 30 Gm. for a man.

11. The daily oral administration of large doses of gluconic acid to dogs and cats for a period of two weeks failed to produce any gross or histologic tissue changes.

12. The continued administration of large oral doses of gluconic acid to normal human subjects also failed to produce any pathologic renal changes, as evidenced by the absence of blood, protein, casts, and sugar in the urine.

13. Gluconic acid and ammonium gluconate appear to be equally effective in lowering the pH of the urine in man in the absence of urinary infection. To produce this effect, single doses of about 10 Gm. or more are necessary, and these cause gastrointestinal disturbances in about one-half of the cases. In individuals with infected urine the effect of these compounds on the pH of the urine is much less certain, more often causing a diminished acidity.

INVESTIGATION OF PROTECTIVE ANTIBODIES PRODUCED BY ORAL ADMINISTRATION OF TYPHOID VACCINE*

H. D. MOOR, M.D., AND LUCILLE BROWN WALLACE, M.S., M.T.
OKLAHOMA CITY, OKLA.

THIS investigation was carried out with the cooperation of the Army Medical School. Colonel J. F. Siler outlined the procedure to be followed and the laboratory work was carried out under the direction of Lieutenant Colonel G. C. Dunham.

The Bacteriology Department of the University of Oklahoma carried out the following steps in the investigation:

1. Twenty-five adult individuals (20 females, 5 males) who gave a negative history for typhoid fever and for antityphoid vaccination were tested.
2. Twenty cubic centimeters of blood were secured from each.
3. The sera were separated and an agglutination titration was run on each serum.
4. The remainder of the sera was then carefully packed in sterile vaccine bottles under strict aseptic precautions and shipped to Lieutenant Colonel G. C. Dunham at the Army Medical School in Washington, D. C.
5. Here under his supervision mouse protection tests were carried out.

Following these preliminary agglutination titrations carried out in our laboratory and the titration of the protective antibodies by Lieutenant Colonel Dunham, each of the 25 individuals was given a course of oral typhoid vaccine consisting of three capsules taken at twenty-four-hour intervals, and containing in each capsule, ten thousand million heat-killed typhoid bacilli, Panama Carrier Strain No. 58. One capsule was taken on three successive mornings, one hour before breakfast.

Two and six weeks after the oral administration each individual's blood serum was titrated in our laboratory for agglutinin antibodies and samples were forwarded to Lieutenant Colonel Dunham in Washington, where they were tested for protection antibodies by the mouse protection tests. The results of these tests appear in Tables I and II.

These results confirm those previously published by us and others regarding the agglutinin antibody content in the blood of individuals orally vaccinated for typhoid fever (Hoffstadt and Thompson,¹ Hoffstadt and Martin,² Pijper and Dan,³ Simons,⁴ Crimm and Short⁵).

The results of the mouse protection tests for protective antibodies in the blood sera of the orally vaccinated individuals were practically 100 per cent negative.

The slight protection given the mice by the blood sera of three of the volunteers can be explained on the basis of experimental error, or it might be due to the "anamnestic" phenomenon.

*From the University of Oklahoma School of Medicine, Oklahoma City.
Received for publication, June 7, 1940.

In a previous publication⁶ we pointed out the advisability of testing the sera of orally vaccinated people by the mouse protection method, as well as trying chemical killing of the vaccine instead of heat killing.

In our previous experiments we did not test for the H agglutinins because we felt at the time that heat killing the vaccine destroyed the H antigen. Crimm and Short, using the same strain of *B. typhosus* in preparing typhoid vaccine for oral administration, and orally administering it in the same way we did, have been able to demonstrate the presence of H agglutinin antibodies for *B. typhosus* in the blood sera of people orally vaccinated.

The combined results of practically all the experiments with oral administration of typhoid vaccine to date show that agglutinin antibodies both O and H for *B. typhosus* are found in the blood sera of individuals following the vaccination.

Agglutinin, precipitin, and lytic antibodies for *B. typhosus* have been demonstrated in the blood sera of people orally vaccinated for typhoid by Hoffstadt, Thompson, and Martin. Protective antibodies as revealed by the mouse protection tests at the Army Medical School, Washington, D. C., failed to show their presence in any significant quantity. Various field trials with oral typhoid vaccine in South America, Africa, and Europe have had encouraging results. It is, therefore, reasonable to state that the oral administration of typhoid vaccine may possibly be an effective method, but at the present time it is not advisable to accept it or to recommend it.

The intradermal method reported by Siler and Dunham⁸ at the Army Medical School and Tuft, Yagle, and Rogers^{9, 10} at the Temple University School of Medicine, furnishes definite evidence that it is effective. It also practically eliminates the most objectionable feature of the subcutaneous administration of typhoid vaccine, namely, the general incapacitating systemic reaction.

COMPLEMENT FIXATION WITH SPECIFIC ALLERGENS IN HAY FEVER

I. PROBLEM, PROCEDURE, DIAGNOSTIC VALUE

M. E. HENSEL, M.D., AND J. M. SHELTON, M.D.
ANN ARBOR, MICH.

IT IS still a moot question whether the treatment of hay fever and asthma with specific antigens immunizes or de-immunizes (desensitizes, de-allergizes). Different methods (skin tests, conjunctival tests, Prausnitz-Küstner reaction) gave highly contradictory results to different investigators.

The first theory offered is that of Noon,¹ who considered the offending protein as a toxin against which the body forms an antitoxin. Noon, therefore, aimed at active immunization and tried to increase the antitoxin titer in the tissues, using the conjunctival test as a means of checking his theory. After each therapeutic inoculation he found a decrease in the degree of conjunctival reaction during the first few days, followed by a rise to a higher level if a

*From the Allergy Clinic, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor.

Received for publication, June 10, 1940.

proper amount of "toxin" had been given. Noon's findings with regard to the negative phase and the following peak of immunity correspond to those of Brieger and Ehrlich,² and of Wright³ in their experiments with bacterial vaccines. Freeman⁴ and Cooke⁵ adopted this view. Pasteur-Vallery-Radot, and Haguénau,⁶ however, obtained opposite results by a different method of treatment. They gave daily intracutaneous injections to an asthmatic patient sensitive to horses and observed that the patient's diminishing susceptibility to the presence of horses was accompanied by a decrease of his skin reactions, which finally disappeared entirely. Cooke,⁵ on the other hand, did not see any decrease of skin reactions during specific treatment, whether the patients were benefited or not. Levine and Coca⁷ investigated the serum of allergic patients by means of the Prausnitz-Küstner reaction (passive transfer). They found that during a short course of pre-seasonal treatment the reactions decreased in some cases, and increased in others. They conclude that their study furnished no proof that the effect of specific treatment of atopic conditions is due to desensitization. Colmes and Rackemann⁸ state that the success of preseasonal specific treatment is independent of the degree of the skin reaction at the end of the course, and that the degree of skin reaction is not related to the total dose given. Black⁹ emphasizes that the question as to what is being done by specific treatment is still open to investigation. Baldwin and Glaser¹⁰ state that there is no correlation between skin reactivity and the success of treatment and decrease of the reactivity of the mucous membranes. The passive transfer gives inconclusive results.

An entirely different method of approach was employed by Walker¹¹ and Albus¹² who used complement fixation tests.

Walker studied a group of 30 patients who by history and skin tests were sensitive to one or several of the following proteins: horse dander, cat hair, wheat, and *Staphylococcus aureus*. The complement fixation with the offending proteins was positive in some patients, negative in others. In all patients who had a positive complement fixation, this was decreased by specific treatment. A negative complement fixation would stay negative throughout the treatment. Nonallergic persons had negative complement fixation. Albus studied 8 hay fever patients who had a positive complement fixation with those pollens (grasses and trees) to which they were sensitive according to history and skin tests. The complement fixation was found negative after a course of pre-seasonal treatment sufficient to relieve the symptoms. Albus claims that the necessity of treatment in the following year may be judged by the result of a complement fixation test performed before treatment is begun.

Contrary to the other methods mentioned, the complement fixation test gave consistent results to those who used it, and appeared to offer an opportunity to study in detail the patient's reactivity during the different phases of specific treatment. We decided, therefore, to adapt Albus' methods to the conditions of the Midwestern States, and to repeat his study on a larger number of patients, and in more extensive fashion.

PROCEDURE

Albus' method is the complement fixation test as modified by Hecht.¹³ It was first applied to allergic patients by Jaffe.¹⁴ Active human serum and un-

sensitized sheep cells form the hemolytic system. Inhibition, in the presence of an antigen, of the normal hemolytic power of the active serum indicates the presence of specific antibodies and is considered a positive test. The method requires determination of the hemolytic titer of each individual serum before the actual test is performed.

Technique.—For the preliminary reaction 0.2 c.c. of the serum and 1.0 c.c. of normal saline were placed into each of ten Kahn tubes and incubated at 37° C. for thirty minutes. Then graded amounts of a 5 per cent suspension of freshly washed sheep blood corpuscles were added, the gradations beginning with 0.1 c.c. of the suspension in the first tube and successively increased in each following tube so that the last tube receives fully 1.0 c.c. of red blood cells. The tubes were incubated once more at 37° C. for thirty minutes, and the reaction was read at the end of this time. The highest amount of sheep cells, which had become completely hemolyzed, was recorded. The procedure for the actual test was similar, but the normal saline was replaced by solutions of the antigen under investigation. One cubic centimeter of graded antigen dilutions was placed into each tube with 0.2 c.c. of serum and incubated for half an hour. After this time a proper amount of sheep cells, as determined in the preliminary test, was added to each tube, and the mixture was incubated once more for thirty minutes. The reaction was read at the end of this time, and again after being placed in the icebox for twenty-four hours. The highest dilution of antigen is recorded which shows nonhemolyzed sheep cells.

Antigens.—Extracts of the dried pollens of short ragweed, orchard grass, and June grass were used as antigens. Normal saline, rather than Coca's solution,¹⁵ was used as the extracting fluid because the presence of a preservative might influence the test. A weighed amount of the pollen was extracted with 100 c.c. of normal saline (for intravenous use) in the icebox at 5° C. for forty-eight hours. The fluid was then filtered through a Seitz filter, and was ready for use if proved sterile in aerobic and anaerobic cultures. Two different extracts were prepared of each species of pollen. An extract of 5 Gm. of pollen in 100 c.c. of saline was called "concentrated," while an extract of 1 Gm. in 100 c.c. was used as "stock fluid" (dilution No. 0). From this solution progressive dilutions were obtained by mixing a measured quantity with an equal amount of normal saline and repeating this procedure with part of the diluted solution. The antigen solutions in Table I were used.

a number of persons in whom pollen sensitization could be excluded were used as controls (Table II).

Twenty-five sera of normal individuals and of allergic patients not sensitive to pollens were tested with ragweed antigen. While some of the sera showed inhibition of hemolysis (complement fixation) with high concentrations of this extract, none reacted with any dilution higher than No. 1 (1:200). On this basis complement fixation with No. 2 and higher dilutions of ragweed extract was considered specific in our later work. Twenty-four of these sera were also tested with orchard grass antigen. Sixteen sera of the same group and six sera of hay fever patients not sensitive to June grass were tested with June grass antigens. Reactions occurred only with concentrated and stock fluids. Therefore, complement fixation with No. 1 and higher dilutions of orchard grass and June grass extracts was considered specific.

b. *Hay Fever and Asthma Cases.*—The sera of 51 patients who had, or had had, symptoms of pollinosis were examined by the complement fixation method. All these patients had been found sensitive to one or more of the pollens by both history and scratch tests. Many patients were examined more than once, and with few exceptions all three pollen extracts were used in each instance.

For our purposes the patients were divided into two major groups: those who had never had specific treatment or who had interrupted such treatment for a prolonged period, and those who were examined while they were receiving perennial treatment at regular intervals. The first group only will be considered in this communication.

There were 25 patients who had suffered from hay fever for from sixteen months to thirty years prior to examination. Eighteen persons of this group had never had specific treatment; 6 patients had had preseasonal and coseasonal treatment in previous years, but had not received injections for periods ranging from seven weeks to eleven months. The results of the complement fixation test were essentially similar in these two classes, and will be discussed together.

Twenty-three patients were sensitive to ragweed, 12 were sensitive to orchard grass, and 11 were sensitive to June grass. Blood for serologic examination was taken usually shortly after, occasionally before, the diagnostic scratch tests were administered. At this first examination 22 of 23 patients sensitive to ragweed showed some degree of complement fixation with ragweed antigen; 11

of 12 patients with orchard grass sensitization reacted with orchard grass extract, and all 11 patients sensitive to June grass showed inhibition of hemolysis with June grass. The general range of antibody titers was definitely higher

in hay fever cases than in the control group, there was a wide variation of reactivity, and only twelve, five, and five tests, respectively, were within the specific range. The amount of reagin in the serum appeared to be independent of the degree of positivity of the skin tests (Cases 4, 7, 22, 25). Neither was the age of the patient, the duration of the disease, nor the time of the year at which the blood was taken in any constant relationship to the antibody titer.

Repetition of the test, however, furnished some interesting findings. In five cases we were able to obtain another blood sample at a later date. Case 13 was re-examined two months after the first serologic test, two days after the administration of positive scratch tests. The antibody titer had increased. Cases 6, 16, and 18 were checked a few days after the first examination which, in these cases, practically coincided with the skin tests. The antibody titer for ragweed had increased in two of them; it was still lower in Case 18, a farmer who was continuously exposed to ragweed in his occupation. It is reasonable to assume that the diagnostic scratch test had brought about a partial increase of floating antibodies in those patients who were not otherwise in contact with the pollens at that particular time of the year. Case 6 was seen once more at the end of the ragweed season without having received specific treatment in the interval. This time she reacted to all three antigens in the highest dilutions. Case 5 had been first examined before the beginning of the ragweed season. Because her history was not entirely significant for ragweed sensitization, and because she had positive skin tests for molds in addition to the one for ragweed, she was started on injections with mold extracts. She spent most of the ragweed season in the northern part of Michigan and was free of symptoms. Three days after returning home she developed a severe asthmatic state which lasted for five days before she was seen at the clinic. At that time complement fixation with ragweed was strongly positive.

COMMENT

The titration of antibodies for diagnostic purposes by the complement fixation test, as it was undertaken in this study on 25 normal persons and 25 hay fever patients, shows that while a positive reaction with higher dilutions of the specific pollen extracts is found in sensitized individuals only, there is a relatively large percentage of allergic persons who have low titers of serum reagins without having had "desensitizing" treatment. The test does not appear to be suitable to replace the skin tests in the diagnosis of hay fever. It promises, however, to be a valuable tool for the investigation of the mechanism of pollinosis.

Our experiments show—in agreement with the results of previous workers—that specific antibodies can be demonstrated in the serum of hay fever patients both in and out of season. It is apparent that skin reactivity and the quantity of floating antibodies do not parallel each other, and that the serum reagins are more variable than the reactivity of the skin, a result which conforms with the experiences of protein sensitization of animals (Kahn). Cases 4, 7, 22, and particularly 25, show in addition that in the same blood sample there may be a high antibody titer for one antigen and a low titer for another; the corresponding scratch tests show just the opposite result. Fluctuations of reagin titer occurred in three of four cases following a diagnostic scratch test. This makes it likely that had the examination been repeated in other instances, posi-

tive complement fixation would have been found in a much larger percentage than our tables suggest. The alteration of the antibody titer following a scratch test tends to emphasize two advantages that a serologic examination has over a skin or mucous membrane test in the investigation of the allergic mechanism. The serologic reaction enables us to test the amount of antibodies available in the body at any precise moment, and it does not influence the allergic state of the patient. The administration of even a minute quantity of the allergen to one of the body surfaces, however, causes the organism to react, and will in itself influence the result of the next examination.

Case 4 suggests, on the other hand, that the antibodies which are demonstrated by the complement fixation test are not identical with the reagins responsible for the Prausnitz-Küstner reaction. In this case a blood sample taken three days after the scratch test showed a positive complement fixation with ragweed, low titers for orchard grass and June grass. A passive transfer performed with the same serum was positive for all three allergens.

SUMMARY

Hecht's modification of the complement fixation test was used to determine the amount of specific antibodies in the blood of patients suffering from hay fever. Extracts of the pollens of short ragweed, orchard grass, and June grass were used as antigens.

Twenty-five normal controls showed only occasional reactions with highly concentrated extracts. Twenty-five hay fever patients who either had received no specific treatment at all, or had received no treatment recently, showed reactions with much higher dilutions of the allergens, particularly if examined repeatedly under varied conditions.

The significance of fluctuations of the antibody titer has been discussed.

AN EVALUATION OF THE IMPORTANCE OF FUNGI IN RESPIRATORY ALLERGY

G. L. WALDBOTT, M.D., K. E. BLAIR, M.D., AND A. B. ACKLEY, Ph.D.
DETROIT, MICH.

CONSIDERABLE attention has been focused recently upon the relation of fungus spores to allergic diseases of the respiratory tract. At times large quantities of wind-borne spores may be present in the air, fungus seasons similar to pollen seasons have been noted; skin tests to fungi are often positive. However, the question as to how much symptoms of respiratory allergy are actually due to molds is still highly controversial. During the past three years we carried out, in collaboration with Ascher,¹ a comprehensive study of this question which included both an air survey and a clinical follow-up study.

AIR SURVEY

A brief review of the air survey is necessary for the present report. One of us (A. B. A.) exposed Sabonraud plates each day for the period of one year. Proper controls were made throughout the duration of the survey by exposure of plates at the same time and under the same experimental conditions 3 feet and 90 miles apart. Other controls included simultaneous exposures at different heights and in twenty-three different habitats for fungi throughout the city, such as in a bakery, butcher shop, pigpen, chicken coop, and barnyard. Clear patterns for the presence of certain fungi were recognized which tended to tally in all these different exposures on certain days and during certain seasons. Individual differences, however, were very pronounced. Precipitation and low barometric pressure tended to free the air temporarily from fungus spores. Inland winds, as well as high pressure, increased the count. Continued

freezing and subfreezing weather inhibited propagation of spores. Among the perennial fungi (Graph 1) *Penicillium*, yeast, and *Torula* produced the greatest number of colonies. *Alternaria* and *Monilia*, while present throughout the year, showed a distinct seasonal increase, namely, *Alternaria* from July to November and *Monilia* from May to November. Another seasonal increase was observed for yeasts and *Torula* in the early part of the year. In June and early July rust was found on slides which we exposed simultaneously with the culture plates, and smut occurred from July through October.

Graph 1.—Air survey. Scale— $\frac{1}{4}$ inch equals 100 colonies. (No count from latter part of February to first part of March due to illness of A. B. A.)

METHODS

In this study the following methods were employed: (1) Intradermal skin tests with fungus extracts. (2) Fungus cultures and microscopic examination of smears from nasal and bronchial secretions. (3) Symptom "calendars" for each patient during the period of the fungus survey. (4) Exposures of fungus plates in patients' homes. We refrained from making extensive passive transfer studies because we found these tests less conclusive than skin tests.

SKIN REACTIONS

Comparison of Individual Fungi.—With the thirteen genera of fungi* most frequently encountered in the air survey, intradermal skin tests were performed on 841 patients with upper respiratory allergy. The dry extracts were prepared according to the method of Feinberg.² The average reactions determined for each fungus per patient are shown in Graph 2.† A total of 580 patients, or 69 per cent of the entire group, gave positive reactions to one or more fungi. Alternaria, Monilia, Epidermophyton, and rust predominated slightly in skin reactivity over the others. Torula and Rhizopus gave the weakest reactions.

Graph 2—Average skin reaction (+ to +++) for each fungus (841 patients).

Comparison in Different Types of Cases.—On the basis of history and clinical behavior the 841 cases were subdivided into the following groups: (1) Patients with seasonal hay fever (267 cases) and asthma (182) due to pollen. (2) Nasal allergy (110 cases) and asthma (219) occurring seasonally but not accounted for by pollen. (3) Perennial upper respiratory allergy, namely, 38 cases of asthma and 25 of vasomotor rhinitis. (4) In addition to these three groups with a total of 841 patients, 39 cases were included for comparative purposes, namely, 28 cases of chronic sinus infection and 11 cases of bronchiectasis. In these patients an allergic basis for the infectious state could not be definitely established. No noteworthy data were detected by thus subdividing our cases. Especially in the second group of seasonal "nonpollen" allergy in which fungi were suspected to be major causative agents, the skin reactions coincided well with those of the other patients. Those of the first group, primarily sensitive to

*According to Jadassohn and others (J. Immunol. 32: 203, 1937), the individual species of a fungus behave antigenically like the others of the same genus. We, therefore, refrained from identification of the species.

†They were obtained by adding all the plus marks in all patients for the respective organism and dividing the total by the total number of patients.

pollen, gave stronger positive reactions to fungi than those in the second and third groups. To our surprise, reactions encountered were by far stronger among the cases with chronic sinusitis than in any other patients.

Comparison With Other Antigens.—In an attempt to compare the total number of skin reactions obtained for fungi with those for other antigens in the 841 patients, Graph 3 was established.* If measured by the standard of skin reactivity, fungi are considerably less important than pollens and epidermals but about equally as important as foods.

Graph 3.—Comparison of reactions to fungi with those of other antigens.

Constancy.—Skin reactions to pollen are known to remain positive for a long time. The minor reactions to foods and epidermals are subject to great variations while the majority of the three- and four-plus reactions to foods remain rather stable (Waldbott and Aseher³). Eighty-one of our patients were tested twice and 15 were tested three times for the same fungi. Only a few of the three- and four-plus reactions remained positive upon subsequent testing. The minor reactions tallied only very rarely with those of the original tests.

CULTURES FROM RESPIRATORY SECRETIONS

Of 442 cultures grown on potato dextrose agar medium of a pH 5.5 (222 from nasal secretions, 220 from bronchial secretions) 26 showed no growth, 18 showed sterile hyphae only, and 124 developed bacterial growth. In 274 cultures fungi were grown. *Penicillium* predominated in 122, then followed *Alternaria* (62), *Monilia* (48), and yeast (42). *Aspergillus*, *Hormodendrum*, and *Torula* were less prevalent. The heaviest growths occurred in October and November. *Hormodendrum*, *Alternaria*, and *Aspergillus* were present only from July through November. In the majority of cases we did not consider positive sputum cultures diagnostic, but merely incidental. It is likely to occur in practically any respiratory secretion. In only 5 patients was the same fungus grown twice. In 9 of the 442 specimens the microscopic examination with and without staining revealed mycelia which we were unable to identify. *Alternaria* spores were found in 3, *Monilia* in 3, and yeast in one.

*Since in our routine testing many more tests for foods are made than for pollen, epidermals, and fungi, we had to put the results on a comparative basis: The total number of plus marks in all patients for one group of antigens was divided by the number of antigens in this group.

SYMPTOM CALENDARS

At the outset of our study every patient was provided with a printed form on which he was to record the degree (one plus to four plus) as well as the dates of his symptoms throughout the year. For several months we checked rather carefully the occurrence of the symptoms with each peak of our fungus curve. When there was a general increase of the fungus content in the air, for instance in late October and November, most patients showed a more or less pronounced tendency to be worse. This we were not able to attribute to one specific fungus, nor did patients react to the majority of fungi encountered in the air on those days. With altered weather conditions, especially strong winds and high barometric pressure, many solid particles of organic and inorganic nature, such as dust, soot, insect parts, were present on the exposed slides. They could have provided these symptoms as well as fungi. The only definite causative agents established by this method were rust and smut.* This is set forth in another publication (Waldbott and Ascher⁴). There were 7 patients who exhibited symptoms only at the height of the rust and smut season of 1938, and 12 who suffered marked exacerbation at the time.

HOME SURVEYS

Patients who suspected factors in their home surroundings as a cause of their allergic symptoms exposed Sabouraud plates in their homes for a quarter of an hour on several occasions. Without exception these plates showed the usual growth of fungi, but no abnormal predominance of a single species could be found. These patients were retested after the identification of the growth on the plate, and treated if the respective fungi produced positive reactions. Again no clear-cut relationship was established between the fungus encountered in the patient's home and his symptoms. This is in line with the fact that, as mentioned above, in simultaneous exposures at 23 different habitats no qualitative difference in the growth was noted.

DISCUSSION

Evidently the prevalence of a certain fungus in the air does not necessarily coincide with its actual clinical significance. Some fungi exhibit greater antigenicity than others. *Alternaria*, for instance, as was also pointed out by Feinberg⁵ and Pratt,⁶ gave the strongest skin reactions. *Penicillium*, which outnumbered all others in the cultures recovered from the air and mucous secretions, was considerably less important clinically. *Epidermophyton*, which grew very scantily on our culture plates, ranked foremost among the fungi as far as skin reactivity is concerned.

In explanation of the more pronounced antigenic activity several possibilities may be offered. Most of the fungus spores giving the strongest skin reactions are larger in size than the weaker reacting ones. Rust and most smuts are spiculated, thus being local irritants when in contact with the mucous membranes. These latter fungi show a seasonal appearance and partial or complete

*Rust and smut do not grow on Sabouraud plates. Their presence was determined by a 1% survey.

absence from the air during the balance of the year. There is usually a sudden increase in their concentration when they first appear in the air. All these features are known to account for more pronounced symptoms with pollen.

True respiratory sensitization due to one single fungus was encountered in only a few cases. This is in agreement with the scarcity of similar reports in the literature. But fungus infections (mycosis), which may or may not be associated with allergy, were found in a considerable number of cases. Since they cannot always be distinguished from true allergic asthma and sinus diseases, their incidence in this series cannot be given. The patients exhibit such symptoms as wheezing, coughing, nasal and sinus catarrhs which are often seasonal, usually occurring in late fall. Episodes of low-grade fever may occur. A family background of allergy and eosinophilia in blood and respiratory secretions may or may not be present. Skin tests for other antigens are negative. The responsible fungus gives positive skin reactions, the degree of which varies with the different stages of the disease. Repeated detection of the same fungus in the cultures is the chief diagnostic criteria. Occasionally the x-ray appearance of the chest may permit the diagnosis, there being an excessive enlargement of the hilum shadows and small sharply delineated focal lesions, especially in the lower portions of the lungs which gives the lungs a peculiarly mottled appearance. Occasionally there are fungus lesions on the skin, especially in the body folds, from which the organisms can be grown. Oral and intravenous administration of iodides may be of diagnostic value since it often affords prompt clinical improvement in certain fungus infections.

SUMMARY

1. The role played by fungi in respiratory allergy (asthma and allergic nasal disease) was investigated by an atmospheric survey of fungi, and a clinical study of 841 patients with upper respiratory allergy was made. This study covered intradermal skin tests, fungus cultures, and microscopic examinations of nasal and bronchial secretions, a follow-up of the dates of the patients' symptoms by means of "symptom calendars," and fungus surveys in the patients' homes.

2. Skin reactions to one or more fungi were positive in 69 per cent of the 841 allergic patients. Fewer positive reactions were obtained to fungi than to pollens and epidermals, but about as many as to foods. The strongest positive reactions to fungi occurred in patients who also reacted strongly positive to other antigens.

3. In the cultures from nasal and bronchial secretions, *Penicillium*, *Alternaria*, *Monilia*, and yeast prevailed. During October and November fungi grew more abundantly from the respiratory secretions than at any other period.

4. Plates exposed in patients' homes revealed no characteristic habitats of fungi in any single case.

5. The follow-up of the dates of symptoms indicates that respiratory allergy due to one single fungus is very rare. More often fungi are complicating factors in multiple sensitive patients with asthma and vasomotor rhinitis. During the summer months the most common offenders are smut, *Alternaria*, and rust. As

such they should be given special consideration in the treatment of hay fever. *Penicillium*, which was by far the most common fungus found in the atmosphere, homes, and mucous secretions, was of relatively minor significance clinically.

6. Some of our cases were found to simulate merely asthma and vasomotor rhinitis. They represented true fungus infections. The diagnostic criteria in these cases are outlined.

10 PETERSBORO

A COMPARISON OF SURFACE TENSION MEASUREMENTS AND HEMOLYTIC ACTIVITY OF GUINEA PIG COMPLEMENT*

J. E. FABER, JR., PH.D., AND L. A. BLACK, PH.D., COLLEGE PARK, MD.

EXPLANATIONS of immunity reactions have frequently been based upon the colloidal nature of sera. The inactivation of complement by heat or exposure to ultraviolet light has been reported to cause an alteration of colloidal state measurable by a lowering of surface tension.^{1, 4} Injections of experimental animals with foreign proteins, bacteria, and gum shellac^{5, 6, 10} have been reported to decrease surface tension, probably through some change in physicochemical equilibrium within the serum, and probably not due to the presence of antibodies. These variations have usually been recorded as "time drops," the difference between initial or dynamic surface tension and static surface tension measured after a two-hour period when all surface active substances are adsorbed in the surface layer. Since a variation in complement potency might be correlated with a change in surface tension, the time drops of a number of sera were determined during a study of guinea pig complement.

Blood serum loses its hemolytic activity when heated to 56° C. According to Zinsser,¹ several investigators reported that during heating there was an aggregation of particles which lowered the surface tension. Upon standing, the complement spontaneously reactivated itself, accompanied by a gradual restoration of surface tension. The gradual deterioration of unheated complement on standing was compared to the slow settling out of colloidal suspensions. Shaking was reported to cause inactivation of complement, probably by coagulation, but whether this is accompanied by a drop in surface tension was not investigated.

*From the Department of Bacteriology, University of Maryland, College Park.
Received for publication, June 10, 1940.

Schmidt² reported that the surface tension of a serum did not permit any inference to be drawn as to its complement activity. Segale³ verified a lowering of surface tension upon heating or aging serum. Ultramicroscopic examination revealed aggregates of particles, whose removal restored the surface tension. The addition of these to fresh sera lowered surface tension but did not change the complement activity. Neither Schmidt nor Segale used the du Noüy tensiometer. Brooks,⁴ using a Traube stalagmometer, found a slight decrease in surface tension of complement after inactivation by ultraviolet light, but believed this was like that found after thermo-inactivation and not the cause of the change in hemolytic power.

Much work on surface tension of serum was done by du Noüy who, through immunization experiments, showed that sera of immune animals gave a greater time drop than normal animals.^{5, 6} Sera of immunized animals reached a maximum time drop in about thirteen days, then decreased and finally disappeared in about thirty days, with further immunization of the same or different kind causing no more change. Thus the injection of an antigen resulted in a physicochemical disturbance measurable by an increased time drop, possibly independent of antibody formation.

Yagle⁷ found little value in surface tension measurements of normal and syphilitic sera and concluded that reagins were not more surface active than other substances in normal sera.

Ramsdell⁸ used a du Noüy tensiometer for surface tension measurements to obtain evidence of a denaturing effect of precipitin reactions upon either antigen or immune serum, and obtained negative results. He⁹ showed an increased time drop with serum from sensitized guinea pigs and concluded that antibody formation could not be involved since the sensitized state remained after the surface tension of the serum had returned to normal.

Following the intravenous injection of gum shellac, Hayman¹⁰ detected an increased time drop and believed this indicated changes in the physicochemical state of plasma.

EXPERIMENTAL

Guinea pigs were lightly etherized and 2 c.c. of heart's blood was aseptically withdrawn for complement. This was placed in a sterile agglutination tube, slanted, allowed to stand at room temperature for one hour, and then placed in a refrigerator (7° to 9° C.) for twenty-four hours before the titer was determined. Each sample was centrifuged to obtain clear serum. The hemolysin, which had a titer of 1:6,000, was obtained from Difco Laboratories.

Corpuscles were obtained from a ewe, blood from the jugular vein being aseptically aspirated into a 30 c.c. syringe, immediately expelled into a sterile flask containing glass beads, shaken for about ten minute to defibrinate the blood, and refrigerated. The defibrinated corpuscles were washed the same day, three times or more, packed by centrifuging for twenty minutes, and made up to a 50 per cent suspension, refrigerated, and used within two days. The corpuscles were made up to a 2 per cent suspension in saline for use in the tests. Throughout the work all dilutions were made with day-old saline only¹¹ prepared from 8.5 Gm. of C. P. sodium chloride and 0.1 Gm. of magnesium chloride, made up to

1,000 c.c. with cold tap water, and autoclaved for thirty minutes at 15 pounds pressure.

Complement Titration.—The complement was titrated by determining the least amount necessary to bring about complete hemolysis of 0.5 c.c. of a 2 per cent suspension of sheep cells in the presence of two units of hemolysin contained in 0.5 c.c. The complement was diluted 1:10 and varying amounts were used, ranging from 0.06 to 0.30 c.c., with 0.02 c.c. intervals. The total volume was made up to 3 c.c. with saline; saline, hemolysin, and complement controls being set up for each titration and titers recorded after a one-hour incubation in a water bath at 37° C.

Surface Tension Determination.—Sera for surface tension measurements were diluted with 0.9 per cent saline, made with C.P. sodium chloride in distilled water. All glassware used in measuring surface tension was soaked for several days in cleaning solution, thoroughly rinsed in distilled water, and dried before use. Determinations were made with a du Noüy tensiometer,¹² using 1.5 c.c. of the diluted serum placed on a watch glass 7.5 cm. in diameter. A measurement was made in about twenty seconds, and after the initial reading the watch glass was set aside for two hours before the second or static reading was made. Subtracting the first reading from the second gave the time drop. The samples of sera were first titrated and the surface tension was then determined after an interval of not more than six hours.

Preliminary surface tension measurements using undiluted serum and dilutions of 1:10, 1:100, 1:1,000, 1:5,000, 1:10,000, and 1:100,000 showed the greatest time drop was at a dilution of 1:10,000, thus agreeing with du Noüy's results on normal and immune sera. Accordingly, all time drops are reported on dilutions of 1:10,000 and at the end of a two-hour period since equilibrium is reached in approximately this time. All measurements were made in a small room free from jarring and air currents, and at a temperature between 21° and 23° C. Between 10 and 15 samples were tested at one time.

Samples.—Samples of sera were obtained from pregnant female, nonpregnant female, and male guinea pigs. Only normal guinea pigs were bled, and their weights varied between 250 and 900 Gm. Feed was removed for eighteen hours before bleeding to avoid chylous sera and only clear sera were used. Samples 1 to 27 were sera of males, the next 18 were taken from females that were not obviously pregnant, and the last 7 samples of sera were from pregnant animals.

The surface tension measurements and hemolytic titers of 52 guinea pig sera are presented in Table I. The males, pregnant and nonpregnant females are listed separately, and the sera are grouped according to titer. Only the time drops and the titers are tabulated.

The differences in time drops of sera from individual males placed in the same group according to titer, and the fact that the differences in time drops between the most potent and least potent sera were no greater than those found in the same titer group, show that the surface tension measurements were without relation to hemolytic activity. Likewise no definite relationship between titers and surface tension measurements of either pregnant or nonpregnant female sera could be established.

TABLE I

COMPARISON OF SURFACE TENSION AND TITER OF GUINEA PIG COMPLEMENT

MALES			FEMALES (NONPREGNANT)			FEMALES (PREGNANT)

14	0.14	11.4						
12	0.16	11.1						
13	0.18	8.1						

*Surface tension measurements were made with sera dilutions of 1:10,000; titrations with 1:10 dilutions.

Time drops of the same value were obtained in the three groups of animals irrespective of titer. If all time drops and titers are compared regardless of their source, such wide variations are apparent that no definite correlation can be found. The two female groups tended to show greater time drops, the meaning of which is obscure. Pregnancy might interfere with the surface tension of sera, but this apparently did not account for the nonpregnant group.

SUMMARY

The hemolytic titers of 27 male guinea pigs ranged from 0.06 to 0.18 c.e., 17 being 0.08 or 0.10 c.e. On the whole, the titers of the 18 nonpregnant females were lower than those of the males, possibly because these females were selected from smaller animals. The highest titer obtained from these females was 0.10 c.e., and the lowest was 0.26 c.e., the 18 samples so distributed between these titers that no one titer group predominated.

Pregnancy definitely lowered the titer of 7 guinea pig complements examined. However, the surface tension as measured by time drops in some instances were no greater than those recorded for nonpregnant females or males with materially higher titers. Nevertheless a larger percentage of sera from females had higher time drops than those from males.

A larger percentage of sera from males showed time drops of less than 10 dynes than was recorded for either pregnant or nonpregnant females. Sixty

per cent of the males showed a time drop of less than 10 dynes, while approximately 27 and 30 per cent of nonpregnant and pregnant females, respectively, had time drops of less than 10 dynes.

It must be concluded that the surface tension, expressed as time drop, of 52 samples of guinea pig complement measured with a du Noüy tensiometer, showed no correlation with hemolytic activity.

THE EFFECT OF CARBON TETRACHLORIDE AND THYROXIN ON THE DEVELOPMENT OF SENSITIVITY TO EGG ALBUMEN AND RAGWEED POLLEN EXTRACTS IN THE GUINEA PIG*

CHARLES L. DUNHAM, M.D., CHICAGO, ILL.

THE present study was undertaken to determine whether acute anaphylactic shock in the guinea pig produced with extracts of low ragweed pollen might be achieved more certainly and consistently than had been reported by other workers.¹⁻⁸ Eagle and co-workers⁸ have demonstrated that by employing adequate doses of extracts of low ragweed pollen approximately 50 per cent of guinea pigs might be sensitized to such a degree that fatal anaphylactic shock could be induced. We decided to attempt sensitization of our animals at a time when they were undergoing profound metabolic disturbances. Under these conditions rapid destruction of the antigen or overproduction of antibodies, factors conceivably having an adverse effect on the development of a high degree of sensitivity, might be altered. Carbon tetrachloride was chosen as one agent because it injures the liver, an organ containing an important part of the reticulo-endothelial system. Thyroxin was used in another experiment

*From the Department of Medicine, University of Chicago.
Received for publication, June 10, 1940.

because of its effect on the metabolism of the organism as a whole. Because attempts to affect the development of sensitivity by producing metabolic disturbance in the test animal at the time sensitizing doses of antigen were administered have been almost exclusively limited to extirpation of organs (Hill and Martin⁹), it seems worth while to report these studies.

There has been to our knowledge only one study on the possible relationship of liver necrosis to experimental anaphylaxis. Paul and Roth,¹⁰ using phosphorus as the toxic agent in guinea pigs, produced results which indicated that acute phosphorus poisoning interferes with anaphylactic shock and that subacute phosphorus poisoning present at the time of sensitization prevents the acquisition of sensitivity to horse serum in 50 per cent of guinea pigs. One other study is of interest in this connection. Mills and Dragstedt,¹¹ in an effort to blockade the reticulo-endothelial system of the liver, obstructed the common bile duct and produced a bilirubinemia in eight dogs. This treatment did not prevent anaphylactic shock. In all but one instance the operation was done at least one week after the sensitizing dose of horse serum had been given. In one dog the common bile duct was obstructed two days prior to sensitization. This animal was successfully shocked twelve days later. No statement was made as to the presence or absence of necrosis in the livers of these dogs. These workers have also demonstrated that blockading the reticulo-endothelial system with India ink and saccharated iron oxide will not prevent anaphylactic shock in dogs.¹² They discussed the conflicting reports of results of blockade in small animals, as summarized by Hill and Martin. Citing some experimental work of their own, they concluded that it is important to administer the shocking dose of horse serum intravenously. The prior injection of dyes seemed to affect absorption of the antigen from the peritoneal cavity. It seemed worth while, however, to investigate the possibility that nonspecific disturbances of liver function might promote sensitization. We, therefore, administered the sensitizing doses of antigen at the time of the maximal effect of nonfatal carbon tetrachloride poisoning.

Képinow and Lanzenberg,^{13, 14} studying the effect of thyroidectomy on anaphylaxis in guinea pigs, concluded that if thyroidectomy was performed prior to sensitization procedures no sensitization resulted, but that thyroidectomy done twenty days after sensitization and seven days prior to shocking did not inhibit anaphylaxis. Moreover, thyroidectomized animals given thyroid substance during the period of sensitization died of anaphylactic shock. Passive transfer studies confirmed their opinion that normal thyroid function was essential to the production of anaphylactic antibodies, but was not essential to anaphylactic shock.^{14, 15} Appelmans¹⁶ reported a few experiments which do not confirm this view. Pfeiffer,¹⁷ however, was able to substantiate the results of Képinow and Lanzenberg. It seemed possible, therefore, that giving sensitizing doses of antigen at a time when the animal was undergoing the profound metabolic disturbances induced by a single massive dose of thyroxin might result in the sensitization of a greater proportion of animals.

METHODS

Phelps and Hu¹⁸ produced definite necrosis of the liver in guinea pigs by the oral administration of 0.66 c.c. of carbon tetrachloride per kilogram of body

weight. We determined, in a series of preliminary studies, that in guinea pigs weighing over 400 Gm., 1.0 c.c. of carbon tetrachloride per kilogram of body weight would regularly produce a definite necrosis of the liver demonstrable on the fifth and seventh days after subcutaneous inoculation. This dosage proved to be too high, for in one series most of the pigs died a day or two after receiving the initial sensitizing doses of ragweed pollen extract, given at the time of, or just prior to, the expected maximum liver damage. In Experiment II a dose of 0.8 c.c. of carbon tetrachloride per kilogram of body weight was used. For small animals, of 300 to 400 Gm. body weight, 0.6 c.c. per kilogram was injected.

The carbon tetrachloride was administered subcutaneously as a 50 per cent solution in olive oil.

The thyroxin solution was prepared freshly a few minutes prior to subcutaneous inoculation by dissolving 10 mg. of Squibb's crystalline thyroxin in one drop of 1 N sodium hydroxide and then making it up to 10 c.c. with distilled water. The egg albumen was a 1:10 dilution of fresh egg albumen in plain physiologic salt solution.

Pollen extracts were prepared by adding the desired amount of low ragweed pollen obtained from Knapp and Knapp to an amount of physiologic sodium chloride solution sufficient to give the desired concentration. This mixture was kept at room temperature for two hours during which time it was agitated repeatedly. It was then placed in a refrigerator. The following day the mixture was filtered through a sterile Seitz filter. The extract was then ready for use. Extracts used for sensitizing were kept in the refrigerator for as long as five days after preparation. Extracts used for shocking were prepared freshly for each day's experiments. Extracts of a 1:20 concentration contained approximately 0.72 mg. of nitrogen per cubic centimeter, and the 1:10 extracts, 1.5 mg. of nitrogen per cubic centimeter. All sensitizing doses were administered intraperitoneally. The shocking doses were given into the jugular vein of the unanesthetized animal. All the guinea pigs used in these experiments were kept on a diet of ground "Alfa Rabbit Flakes" with daily greens in the form of lettuce, celery tops, and occasionally cabbage. The animals were weighed at the time of their first inoculations. With the exceptions noted later they were in good health for the duration of the experiments.

EXPERIMENTAL

Experiment I. Eight guinea pigs, weighing from 450 to 680 Gm., were given 1 c.c. of carbon tetrachloride per kilogram of body weight. On the third and sixth days following, 0.5 c.c. of a 1:10 egg albumen solution was injected intraperitoneally. On the twenty-first day after the last injection 0.5 c.c. of a 1:10 egg albumen solution was given intravenously. Six animals died within four minutes of the injection in typical acute anaphylactic shock. Autopsy confirmed the diagnosis. Treatment with carbon tetrachloride did not interfere with the development of sensitivity to egg albumen.

Experiment II. (Table I) We next treated 6 male and 6 female guinea pigs with 0.8 c.c. of carbon tetrachloride per kilogram of body weight. Sensitizing doses of a 1:20 extract of low ragweed pollen were given on the third, fifth, and

seventh days following administration of the carbon tetrachloride. Simultaneously a similar group of 12 control animals was given sensitizing doses. One animal (206) in the first group died of hemorrhage, the result of administration of the first dose of pollen extract on the third day following injection of carbon tetrachloride. Microscopic study of the liver from the animal showed a large accumulation of fat and considerable necrosis about the centers of the liver lobules. The shock doses of fresh 1:10 extract of low ragweed pollen were

given intravenously on the twentieth and twenty-first days following the last sensitizing dose. The extracts were tested on normal animals for possible toxicity, but the results were negative. As will be seen from Table I, 50 per cent of the animals not treated with carbon tetrachloride were rendered sufficiently sensitive to die in acute anaphylactic shock. Only 2 of the 9 animals treated with carbon tetrachloride, and surviving until the shock date, died from the intravenous injection. Apparently carbon tetrachloride as administered did not favor the development of sensitivity to extracts of ragweed pollen.

Experiment III. (Table II.) Six guinea pigs, weighing 350 to 450 Gm. each, were given 35 mg. of thyroxin subcutaneously. Two, twenty-four, and forty-eight hours later, 1 c.c. of a 1:20 extract of low ragweed pollen was given intraperitoneally. Three weeks later 3 of the 6 animals died in typical acute anaphylactic shock following intravenous administration of 0.5 c.c. of 1:10 pollen extract. These results are similar to those obtained in the control group in Experiment II.

SUMMARY

1. Treatment of guinea pigs with carbon tetrachloride, and the administration of sensitizing doses of egg albumen at the time of maximal anatomic change, did not prevent the acquisition of sensitivity to egg albumen in 6 of 8 animals.

2. Two of 9 guinea pigs given sensitizing doses of an extract of low ragweed pollen at a time when they were suffering from carbon tetrachloride poisoning died from typical anaphylactic shock after intravenous administration of pollen extract twenty-one days later.

3. Fatal anaphylactic shock was produced with simple saline extracts of low ragweed pollen in 6 of 12 normal guinea pigs.

4. Three of 6 guinea pigs receiving sensitizing doses of extracts of low ragweed pollen at a time of maximal effect from a single massive dose of thyroxin died in typical anaphylactic shock after receiving the pollen extract intravenously.

CONCLUSION

1. Carbon tetrachloride as employed in these experiments does not appear to inhibit the sensitization of guinea pigs to egg albumen. On the other hand, it does not favor the development of sensitivity to extracts of low ragweed pollen.

2. Thyroxin, as used in these experiments, does not appear to affect the development of sensitivity to extracts of low ragweed pollen.

3. One-half cubic centimeter of a simple saline extract of low ragweed pollen, containing approximately 0.75 mg. of nitrogen, is capable of producing typical fatal anaphylactic shock in sensitized guinea pigs.

A CASE OF *STRONGYLOIDES STERCORALIS* INFESTATION*

GEORGE R. BODON, M.D., ROCHESTER, N. Y.

THE incidence of *Strongyloides stercoralis* infestation is rare in the northern parts of the United States. Ginsburg reported a case in Pennsylvania, and Cadham reported one in Winnipeg, Canada. The parasite is more common in the subtropical and tropical countries and is quite common in the southern parts of the United States. Faust estimated that 6 per cent of the clinic population is infested in New Orleans.

The life cycle of this parasite belonging to the nematode group is quite similar to the *Ankylostoma duodenale*. The female larvae live in the duodenum and jejunum. From the eggs the rhabditoid larvae develop. These in turn may either develop into the strongyloid larvae (infesting forms) or into male or female rhabditoid larvae. These copulate and the eggs burst into the first rhabditoid larvae, and the life cycle starts all over again. The infestation occurs either through the skin by the strongyloid larvae or through the oral cavity. From the skin the larvae get into the blood stream, lungs, trachea, esophagus, and the small intestine.

The case presented here is of interest because it occurred in New York State where the incidence of *Strongyloides* infestation is rare and because its clinical aspects are unusual.

*From the Department of Laboratories, St. Mary's Hospital, Rochester.

Read before the Twenty-fourth Annual Meeting of the New York State Association of Public Health Laboratories, May 20, 1940, Rochester, N. Y.

Received for publication, June 14, 1940.

CASE HISTORY

M. M., a 45-year-old woman, was born in Italy and migrated to this country twenty years ago with her husband. Since that time she has lived in East Rochester. She has three children.

She gave a long previous history of uncertain abdominal pain; she vomited at times and was sometimes jaundiced, the latter being only her own observation. For these uncertain complaints she was hospitalized several times in different hospitals of this city and underwent three abdominal operations: in 1933 cholecystectomy and appendectomy, in 1935 and again in 1938 exploration for adhesions. All these operations showed negative findings. One blood count, however, done in 1933 showed an eosinophilia of 10 per cent.

Fig. 1.

Fig. 2.

Fig. 1.—Rhabditoid larva of *Strongyloides stercoralis*. Low power.

Fig. 2.—Oral end of the parasite. a, First cylindrical dilatation. b, Second bulbous dilatation with chitinous Y. High power.

Fig. 3.

Fig. 4.

Fig. 3.—Body part of the parasite with primitive genital organ (a). High power.

Fig. 4.—Tail end with anal opening (a). High power.

On admission to St. Mary's Hospital on Jan. 30, 1940, she complained of colicky pain, starting in the right upper quadrant and sweeping across the abdomen to the left side. The pain was also felt in the back. About one hour after the onset she vomited some bloody material.

The physical examination was essentially negative. Pressure in the left lower quadrant produced pain in the epigastrium.

The red blood cell count and hemoglobin showed a slight hypochromic anemia. The white blood cell count ranged between 6,000 and 8,000, with a marked eosinophilia of 25 to 29 per cent eosinophile cells. The urine was negative. Routine blood chemistry and the Wassermann reaction were negative.

The first stool examination did not show any parasites, but a large number of Charcot-Leyden crystals. The second stool examination after administration of a saline laxative showed numerous vividly motile nematodes. These parasites were from 200 to 300 microns long and showed marked wriggling motions (Fig. 1). Under high power the oral end showed a short mouth which opens into the esophagus, showing first a cylindrical then a bulbous dilatation followed by the intestine (Fig. 2). In the body on both sides of the intestine ellipsoid structures could be seen constituting the primitive genital organs (Fig. 3). The tail end was pointed and on the base of the pointed tail a cuticular elevation was found which formed the anal opening (Fig. 4). On the basis of these characteristics the parasite could be classified as the first rhabditoid larva of *Strongyloides stercoralis*.

I kept the stool specimens for twenty-four hours in the incubator (37° C.) and by examining the stool specimen I found that the larvae developed into the strongyloid forms. These larvae were much longer than the previous ones and showed well-coordinated boring motions (Fig. 5). After these findings repeated stool examinations were performed and larvae were always found to be present. Gastric analysis and sputum examinations were also done, but these did not reveal the presence of parasites. A skin test with trichinella antigen was positive in 1:1,000 dilution (group reaction).

The treatment consisted of duodenal lavage and gentian violet tablets, 1 grain three times daily. The patient was not very cooperative; she left the hospital and repeated stool examinations still show the presence of the parasite.

Fig. 5.—Strongyloid form of the parasite. Low power.

The stools of the husband and the children were also examined, and the parasite was found to be present in the husband's stool. The blood count of the husband showed eosinophilia of 10 per cent, but otherwise he did not show any symptoms which could be related to the presence of the parasite.

DISCUSSION

Both individuals undoubtedly acquired the parasite in Italy, where the presence of the parasite is known, and they harbored it in their intestines all the time. In the husband it seemingly did not cause any symptoms, except the slight eosinophilia. It is somewhat more difficult to relate the parasite as an etiologic factor to the clinical symptoms in the woman. We do not have a history of an initial itch or eczema at the time of infestation. This condition, however, may be easily overlooked by a woman doing heavy housework. On the other hand, the infestation may have occurred by mouth.

According to the literature, the *Strongyloides stercoralis* is well accepted as a causative agent of diarrhea. The first cases reported were the so-called "Cochin-China" diarrhea in soldiers by Normand. There are also several fatal cases of Strongyloidosis reported in which post-mortem examinations were

performed. Ophuls found the larvae in the intestinal wall and in the mesenteric lymph nodes. Gage found them in the lymph spaces of the duodenal wall. Proes found them in his case in the pleural effusion, pericardial fluid, and in the blood.

Both types of larvae have very intensive motion capacities, and there is no reason why they could not get into the channels connected with the gastrointestinal tract. It is very easily possible that the parasite might get actively or passively into the lumen of the appendix and even without causing a true "appendicitis," through the irritative action of their presence cause appendicular colic which might be easily interpreted as an acute appendicitis.

In the same manner they might migrate into the gall ducts or the gall bladder and cause symptoms of a gall-bladder disease. Nisbet reported a case in which the worm caused obstructive jaundice. There is no reason why they could not get in the same manner into the pancreatic duct and add to the uncertainty of the abdominal symptoms.

The negative findings of the removed surgical specimens and the negative findings at the explorations, together with the preservation of the symptoms after the operations, are enough proof that the patient did not have a true cholecystitis or appendicitis or any other condition which would have resulted in pathologic changes of the abdominal organs. In my opinion the uncertain abdominal symptoms were caused by the presence of the parasite. As far as her present symptoms are concerned, the question is undecided as to whether they are caused by the presence of the parasite or whether they are only neurotic sequelae after her three previous abdominal operations. It is a known fact that individuals harboring parasites develop severe neuroses.

SUMMARY

A case of an Italian immigrant woman is presented in which the stool examinations revealed rhabditoid larvae of *Strongyloides stercoralis*.

It may be assumed that the parasite caused uncertain abdominal symptoms for which the gall bladder and the appendix were removed. Later two laparotomies were performed for the persistence of symptoms, which were thought to be due to postoperative adhesions. All operations resulted in negative findings.

RELATION OF THE MACRONUCLEOLUS AND NUCLEONUCLEOLAR RATIO OF CANCER TO HISTOLOGIC GRADING*

ANTONIO E. MENDES FERREIRA, M.D.†
ROCHESTER, MINN.

THE pathologic diagnosis of cancer has interested many students, and the practical value of such a diagnosis depends on the early recognition of the condition. For this reason, the attention of pathologists during the last few years has been focused on the cell as the unit of cancerous tissue. Because there has been no reliable chemical or serologic test for cancer, the proper treatment has been based on an early clinical suspicion of the disease, its early pathologic recognition, and the determination of the degree of malignancy. Since Virchow established cellular pathology, pathologists have tried to find in the cells of the cancerous tissue some signs on which they could rely for diagnosis, particularly in the early stages of the disease.

After reading the papers of MacCarty dealing with the diagnosis of cancer on the basis of the macronucleolus of its cellular constituents, and the papers of Broders on the grading of malignancy according to the percentage of cell differentiation, I began to study many specimens of fresh cancerous tissue. The work of MacCarty and the work of Broders not only are of great practical value but also are very interesting from a scientific standpoint, and are closely related. The more slides I studied, the more strongly was I convinced that there was really a cancer cell which had a markedly increased nucleolar substance and that in the great majority of cases the amount of that substance varied according to the degree of malignancy. It was on this basis that the present work was done. It attempts to prove that there is a marked increase of nucleolar material in the cancer cell and that the amount of this material is directly proportional to the degree of malignancy.

The presence of one or more large nucleoli in the cells of embryonic and regenerative tissues, and in any normal tissue which is metabolically very active, suggests that the increased size of the nucleolus is a direct consequence of the great cellular activity. As cellular division is one of the greatest expressions of cellular activity, it seems reasonable to admit that any condition in which cellular division is active would afford good opportunity for studying the variation in the size of the nucleolus. It was with this in mind that many months were spent trying to make normal and cancerous tissues grow in vitro. Tissue cultures are, perhaps, the best field in which to study cellular metabolism and cellular division, because cells in vitro grow without body control in a fashion somewhat comparable to the growth of cancer in the body. Unfortunately, because of technical difficulties very few of the cultures grew well, but the few that grew confirmed what has been seen in pictures and descriptions of cultures

*From the Mayo Clinic, Rochester, Minn.

Received for publication, June 18, 1940.

of tissues in vitro—large cells, which had a large nucleus and very large nucleolus.

In 1851 Lebert pointed out that cancer cells possessed one or more large nucleoli, but Vögel, Bennett, and Virchow did much to obscure his work, and the macronucleolus in cancer cells was entirely forgotten until MacCarty in 1923,²² after an exhaustive and interesting research again called attention to the importance of the macronucleolus in the diagnosis of cancer. In a series of papers written from 1923 to 1937, MacCarty²³⁻²⁶ described the "cancer cell" and stressed its characteristics (spheroid or oval form, large nucleus, single or multiple large nucleolus, and low nucleonucleolar ratio), as well as a manner of distinguishing the cells of tertiary cytoplasia from the cells of secondary and primary cytoplasia (MacCarty). However, he repeatedly said that cells of secondary cytoplasia and cancer cells are morphologically very much alike; the only difference is that the former remain in the acini while the latter invade the surrounding stroma. MacCarty and his co-workers continued their study of the nucleonucleolar ratios in malignant and nonmalignant tissues. In 1933 MacCarty, Haumeder, and Berkson made a preliminary report on a series of actual measurements of the nuclear and nucleolar areas and corresponding ratios. They expressed the opinion that the difference between the nucleolar areas in malignant cells and nonmalignant cells is greater than that between the nuclear areas. They said that the nucleonucleolar ratio in malignant cells varies from 1:5 to 1:17, while in nonmalignant cells the ratio varies from 1:13 to 1:45.

In the latter years nuclear and nucleolar areas with the corresponding ratios have been determined in different organs obtained in the laboratory of MacCarty, by Haumeder, McCormack, Naidu, Strohl, Kaump and Fairchild, Kroeze, Cohen, Lofgren, Page, Smith, Campbell, Farthing, and Frugoni. All these authors have definitely confirmed the work of MacCarty,¹⁰ who recently submitted a paper for publication in which he condensed the results of their biometric studies. Similar observations have been made by Stenius, Castren, Saxen, Quensel (1928), Karp (1932), Fidler (1935), and Von Haam and Alexander (1936).

MacCarty recently said: "Microscopic grading has been in existence ever since tissues and tumors have been studied with the aid of microscopes." However, one can say that the real microscopic grading of tumors began in 1920,^{2, 5} when Broders made his first report on the subject. In 1925, after nine years' experience in the grading of epitheliomas, Broders said that a slight modification should be made in his former classification. Thus, tumors should be called "grade 1" when undifferentiation ranges from 0 to 25 per cent, "grade 2" when undifferentiation ranges from 25 to 50 per cent, "grade 3" when undifferentiation ranges from 50 to 75 per cent, and "grade 4" when undifferentiation ranges from 75 to 100 per cent.

In determining the degree of malignancy Broders also considered the number of mitotic figures and the number of cells which have single, large, deeply staining nucleoli (one-eyed cells). Later, in emphasizing the practical value of grading and advising the type of treatment according to grade of malignancy, he said that grade 1 tumors show practically no tendency to metastasize, while grade 4 cancers, metastasize quickly and sooner or later prove fatal. Grade 2

and grade 3 cancers occupy a place between grade 1 and grade 4 as far as metastasis and postoperative results are concerned.

Other methods of grading of tumors, which have been recommended by different authors, are based on cellular differentiation alone or on this and other pathologic and clinical factors. The grading system of Broders, which is the method most often employed in this country, was followed in this work.

MATERIAL AND METHODS

Only human tissues which had been removed surgically were used in this study. The material included 119 malignant and 45 nonmalignant tissues from different organs and tissues, including those obtained from a four-month fetus. Both malignant and nonmalignant tissues were obtained from the thyroid gland, breast, stomach, liver, rectum, sigmoid colon, ovary, endometrium, and cervix uteri. The fetal tissues included the thyroid gland, stomach, liver, and rectum. Only epithelial tissues and tumors of the same origin were studied. The malignant tumors included adenocarcinoma, scirrhus carcinoma, papillary adenocarcinoma, and squamous-cell carcinoma (epithelioma). All the growths were primary except those found in the liver, where metastatic growths also were used. The nonmalignant tissues included normal tissues, subacute and chronic inflammation, hyperplasia, and benign tumors (polyps, adenomas, fibroadenomas, and cysts). As soon as the tissues were obtained from the operating room they were placed in a 10 per cent solution of formalin for fixation. Twenty-four hours later frozen sections from 5 to 10 microns thick were cut and stained with hematoxylin and eosin. The sections were studied histologically and cytologically with low, medium, and high-power objectives, and the malignant tumors were graded according to the classification of Broders.* An attempt was made to obtain approximately the same number of tumors of each grade from each organ. However, this was difficult and even impossible in certain organs. In the thyroid gland, breast, and rectum there were found carcinomas of every grade from 1 to 4. Grade 1 carcinoma very rarely occurs in the stomach and liver. Carcinoma of the ovary most frequently is grade 1 or 2, occasionally it is grade 3, but very rarely grade 4. The most frequent grades of carcinoma found in endometrium are 1 and 2, but grade 3 or 4 carcinoma occasionally may be found in this situation. On the contrary, in the uterine cervix the usual grades encountered are 3 and 4, and grades 1 and 2 only rarely. The cytologic studies were made by using an oil-immersion lens of a Spencer microscope (objective 1.8 mm., N.A. 1.25, tube length 150 mm., and ocular 10 \times). In making the biometric studies a camera lucida was mounted on this microscope, and the contours of the shadows of the nuclei and nucleoli were projected on paper and carefully traced with a sharp pencil. From each section of both malignant and nonmalignant tissue, 20 cells were traced; four cells were chosen in each of five different microscopic fields. These were the cells which had the largest nucleoli. The tracings of the nuclei were measured directly by a planimeter to obtain their areas. Since many nucleoli were small it was necessary to enlarge them in order to obtain measurable tracings. This was done with a camera lucida mounted on a

*The grades of the carcinomas of the breast, stomach, and ovary were kindly checked by Dr. A. C. Broders.

Spencer microscope (objective 48 mm., tube length 250 mm., and ocular 1x). The tracings that were obtained were also measured by a planimeter and the areas were registered. The magnification of this microscope and camera lucida was found to be 42 diameters; therefore, it was necessary to divide the areas of the nucleoli by 42 in order that the magnification might correspond to that employed in the measurement of the nuclei. To obtain the actual areas of the nuclei and nucleoli in square microns, it was necessary to correct the planimeter readings by taking into consideration the magnification of both microscopes, the camera lucida, and the constant of the planimeter.

Under the same conditions as the cells were drawn, a known space of a micromillimeter scale was projected on paper by means of the camera lucida, and the projections were traced and measured. The magnification of the microscope, which was determined in this manner, was found to be 1,800 diameters. The calibration of the planimeter was such that a circular area of 100 sq. cm. represented 2,500 planimeter units. Each area of the planimeter reading was multiplied by a constant that was obtained by using the following formula:

$$\frac{\text{Value for one planimeter unit}}{(\text{Magnification of the microscope})^2} = K.$$

After the actual areas were obtained, it was necessary only to divide the areas of the nuclei by those of the nucleoli in order to obtain the corresponding nucleonucleolar ratio. It is necessary to explain why the quotient

$\frac{\text{average nuclear measurement}}{\text{average nucleolar measurement}}$ does not correspond, except by chance, with the

ratios given. The reason is that the calculation $\frac{\text{average nuclear measurement}}{\text{average nucleolar measurement}}$ was not made. Instead, the nuclear measurement of each cell was divided by the nucleolar measurement of each cell, and these quotients were averaged. The divisions originally were carried out to three decimal places but were contracted later so that it would be necessary to print only one or two decimal places. These contractions caused some lack of correspondence, more apparent than real, between the results of calculations made in the various possible ways.

RESULTS

It would be outside of the purpose of this work to describe the histologic arrangement of the cells in the normal, inflammatory, and neoplastic tissues studied. A description of this arrangement may be found in textbooks and various papers. However, it seems appropriate to consider briefly the variations in size, shape, and number of the nucleoli. Ehrlich recently said, that "the nuclear sizes of normal tissues are by no means constant." The same can be said about the size of the nucleolus. The nucleolus was not easily seen in the cells of all normal tissues. Fresh specimens of the resting breast, which were stained with polychrome methylene blue, and fixed specimens which were stained with hematoxylin and eosin, rarely showed nucleoli. On the contrary, the nucleoli were conspicuous in most of the cells of other tissues studied, particularly in fresh tissues. Normal cells usually contained a single, round, well-

defined nucleolus which appeared very small in relation to the nucleus. Occasionally, two or three nucleoli were seen within the nucleus, particularly in the normal stomach and rectum. The cells of inflammatory tissues and benign tumors almost always contained round or elliptic nucleoli. The size of the nucleoli depended on the type of the cell (primary or secondary cytoplasia of MacCarty), but the nucleoli almost always were larger than those of the corresponding normal tissue. The greatest variation in size, form, and number of the nuclei and nucleoli was seen in the cells of secondary cytoplasia and in those of cancer. In these cells two or three nucleoli frequently were seen within the nucleus. Occasionally, as many as six could be counted. These nucleoli usually were very large in relation to the nucleus; they were round or elliptic, and occasionally were elongated or somewhat triangular. When the nucleoli were multiple, one usually was much larger than the others.

The results of the biometric studies are reported separately for each organ.

Thyroid Gland.—In nonmalignant lesions of the thyroid gland the average areas of the nuclei and nucleoli were 28.13 and 1.08 square microns, respectively, and the average nucleonucleolar ratio was 30.4 : 1. In malignant lesions the average areas of the nuclei and nucleoli were 51.7 and 4.29 square microns, respectively, and the average nucleonucleolar ratio was 13.5 : 1. In carcinoma the areas of the nuclei varied from 32.45 to 76.0 square microns, and the areas of the nucleoli varied from 1.81 to 8.9 square microns. The nucleonucleolar ratio varied from 6.7:1 to 22.4:1. In all nonmalignant lesions, except exophthalmic goiter, the average areas of the nuclei and nucleoli were smaller than the smallest areas of the nuclei and nucleoli in carcinoma. In exophthalmic goiter the average areas of the nuclei and nucleoli were larger than the smallest areas of the nuclei and nucleoli in carcinoma. In thyroiditis and colloid adenoma the average nucleonucleolar ratio was more than three times as great as it was in carcinoma. In the fetal thyroid gland and in exophthalmic goiter the average nucleonucleolar ratio was less than the largest nucleonucleolar ratio in carcinoma.

The areas of the nuclei and nucleoli and the nucleonucleolar ratio in the different grades of carcinoma of the thyroid gland are shown in Table I. This table is of interest mainly because it shows that the average area of the nucleoli increases gradually and the nucleonucleolar ratio decreases as the grade of malignancy increases.

TABLE I

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE THYROID GLAND

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO		
		NUCLEI			NUCLEOLI			SMALLEST	LARGEST	AVERAGE
		SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE			
1	3	40.8	72.1	53.0	1.8	3.3	2.4	21.3:1	22.4:1	21.8:1
2	5	36.4	69.4	47.5	2.1	5.9	3.7	10.4:1	16.3:1	12.5:1
3	5	45.2	66.3	56.3	3.4	6.7	5.0	9:1	13.2:1	11.5:1
4	5	32.4	76.0	49.9	3.6	8.9	5.9	6.7:1	9.2:1	8.3:1
	18			51.7			4.2			13.5:1

Breast.—In the study of the breast the results were rather similar to those of the study of the thyroid gland. In nonmalignant lesions of the breast the average areas of the nuclei and nucleoli were 29.87 and 1.26 square microns, respectively, and the average nucleonucleolar ratio was 23.7:1. In carcinoma of the breast the average areas of the nuclei and nucleoli were 54.81 and 4.57 square microns, respectively, and the nucleonucleolar ratio was 13.7. Examination of inflammatory lesions that were associated with primary cytoplasmia revealed that the average areas of the nuclei and nucleoli were considerably smaller than the smallest areas of the nuclei and nucleoli in carcinoma. The average nucleonucleolar ratio in these inflammatory lesions was almost twice as large as the largest nucleonucleolar ratio in carcinoma (36.6:1 and 20.8:1). On the contrary, in inflammatory lesions that were associated with secondary cytoplasmia the average area of the nucleoli closely approximated the smallest area of the nucleoli in carcinoma (2.04 and 2.2 square microns), and the average nucleonucleolar ratio was much lower than the largest ratio in carcinoma (15.8:1 and 20.8:1) and closely approximated the average nucleonucleolar ratio in carcinoma (15.8:1 and 13.7:1). In benign tumors that were associated with primary or secondary cytoplasmia the average areas of the nuclei and nucleoli were somewhat smaller than the smallest areas of the nuclei and nucleoli in carcinoma. In benign tumors in which there was primary cytoplasmia the average nucleonucleolar ratio was much larger than the largest ratio in carcinoma (30.4:1 and 20.8:1), but in benign tumors in which there was secondary cytoplasmia the average nucleonucleolar ratio was slightly smaller than the largest ratio in carcinoma (19.3:1 and 20.8:1). In carcinoma the areas of the nuclei ranged from 37.32 to 93.89 square microns, the areas of the nucleoli ranged from 2.2 to 13.48 square microns, and the nucleonucleolar ratio varied from 4.6:1 to 20.8:1 (Table II).

TABLE II

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE BREAST

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO		
		NUCLEI			NUCLEOLI			SMALLEST	LARGEST	AVERAGE
		SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE			
1	5	40.9	57.0	49.1	2.3	3.0	2.6	15.1	20.8:1	18.4:1
2	6	39.6	56.8	47.2	2.2	5.1	3.3	10.9:1	17.8:1	14.7:1
3	5	37.3	93.8	66.1	4.2	6.1	5.6	6.1:1	14.9:1	11.8:1
4	5	52.4	72.7	57.0	4.1	13.4	6.6	4.6:1	13.2:1	10.1:1
	21			54.8			4.5			13.7:1

The results of biometric study of carcinoma of the breast were similar to those obtained in the study of carcinoma of the thyroid gland (Table I). The area of the nuclei did not have any relation to the grade of carcinoma, but the average area of the nucleoli increased gradually and the average nucleonucleolar ratio decreased as the grade of malignancy increased.

Stomach.—In nonmalignant lesions of the stomach the average areas of the nuclei and nucleoli were 38.2 and 1.8 square microns, respectively, and the

average nucleonucleolar ratio was 21.2:1. In carcinoma the average areas of the nuclei and nucleoli were 52.6 and 3.9 square microns, respectively, and the average nucleonucleolar ratio was 13.4:1. The areas of the nuclei and nucleoli of normal gastric tissue were rather constant and were much smaller than the respective areas in carcinoma (Fig. 1). The average nucleonucleolar ratio of

Fig. 2.

Fig. 2.—Primary cytoplasia in the edges of a gastric ulcer. (Photomicrograph kindly loaned by Dr. W. C. MacCarty.)

Fig. 3.—Secondary cytoplasia in the edges of a gastric ulcer. (Photomicrograph kindly loaned by Dr. W. C. MacCarty.)

normal gastric tissue was almost three times as large as it was in carcinoma (36.2:1 and 13.4:1). In fetal gastric tissue the average area of the nuclei was about the same as it was in carcinoma, the average area of the nucleoli was slightly larger than the smallest area of the nucleoli in carcinoma, and the nucleonucleolar ratio occupied an intermediate position between the ratios obtained in a study of normal gastric tissue and carcinoma of the stomach. Bio-

metric studies of inflammatory lesions that were associated with primary cytoplasia revealed that the nucleoli were somewhat larger than those found in normal gastric tissue (Fig. 2); the average nucleonucleolar ratio was similar to that obtained in a study of fetal gastric tissue. The material included only one benign tumor of the stomach that was associated with primary cytoplasia. In this tumor the nuclei and nucleoli were larger than those in normal gastric tissue, but the average nucleonucleolar ratio was slightly smaller than that of the normal gastric tissue. In benign tumors that were associated with secondary cytoplasia the measurements usually corresponded very closely to those obtained in grade 2 carcinoma. The same was true of gastric ulcers that were associated

FIG. 4.—Carcinoma, grade 2, of the stomach ($\times 1,000$).

with secondary cytoplasia (Fig. 3). In carcinoma the smallest areas of the nuclei and nucleoli were 36.2 and 2.3 square microns, respectively, and the smallest nucleonucleolar ratio was 9.9:1. The largest areas of the nuclei and nucleoli were 74.9 and 6.7 square microns, respectively, and the largest nucleonucleolar ratio was 17.6:1 (Table III). The gastric material did not include a specimen of grade 1 carcinoma. A study of the material revealed that in carcinoma of the stomach the average area of the nucleoli increases and the nucleonucleolar ratio decreases as the grade of malignancy increases. The cells encountered in the different grades of carcinoma are shown in Figs. 4, 5, and 6.

Liver.—The biometric studies of the liver were of particular interest as there was a slight difference in the nucleonucleolar ratios in all lesions, including carcinoma. In nonmalignant lesions of the liver the average areas of the nuclei

and nucleoli were 33.0 and 1.9 square microns, respectively, and the average nucleonucleolar ratio was 16.9:1. In malignant lesions the average areas of the nuelei and nucleoli were 64.6 and 6.1 square microns, respectively, and the aver-

Fig. 5.—Carcinoma, grade 3, of the stomach ($\times 1,000$).

Fig. 6.—Carcinoma, grade 4, of the stomach ($\times 1,000$).

age nucleonucleolar ratio was 11.6:1. In the fetal liver the nuelei and nucleoli were small in comparison with the very large nuelei and nucleoli in carcinoma. However, the nucleonucleolar ratio was not much higher than was the average ratio in all grades of carcinoma (14.1:1 and 11.6:1); in fact, the average nucleo-

TABLE III

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE STOMACH

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO		
		NUCLEI			NUCLEOLI			SMALLEST	LARGEST	AVERAGE
		SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE

	18			52.6			3.9			13.4:1

nucleolar ratio in the fetal liver was higher than the smallest ratio in grade 2 carcinoma (15.4:1 and 14.1:1). In normal hepatic tissue the nuclei and nucleoli varied a great deal in size, but they were rather large. The average nucleonucleolar ratio was low; it was only 6.1 more than the average ratio in carcinoma and only 2.3 greater than the average ratio in grade 2 carcinoma. In inflammatory lesions the nuclei and nucleoli were moderately large, and the nucleonucleolar ratio was low (19.0:1), but contrary to what was found in most of the other organs that were studied, the nucleonucleolar ratio was larger than that encountered in normal hepatic tissue. In carcinoma of the liver the areas of the nuclei varied from 42.5 to 88.4 square microns, the areas of the nucleoli varied from 3.0 to 10.6 square microns, and the nucleonucleolar ratio varied from 6.7:1 to 18.1:1 (Table IV). The hepatic material did not include a specimen of

TABLE IV

	12			64.6			6.1			11.6:1

grade 1 carcinoma. A study of the material revealed that the average area of the nucleoli increases and the nucleonucleolar ratios decrease as the grade of malignancy increases. There was no relation between the areas of the nuclei and the grade of carcinoma.

Rectum.—In nonmalignant lesions of the rectum the average areas of the nuclei and nucleoli were 40.6 and 1.8 square microns, respectively, and the average nucleonucleolar ratio was 22.5:1. In carcinoma the average areas of the nuclei and nucleoli were 62.6 and 7.5 square microns, respectively, and the average nucleonucleolar ratio was 11.0:1 (Table V). A study of the fetal rectum

TABLE V

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE RECTUM

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO

	19			62.6			7.5			11:1

disclosed that the nucleoli were relatively large; in fact, they were almost as large as the smallest nucleoli in carcinoma. The nuclei also were large and the nucleonucleolar ratio was high. The material included two inflammatory lesions of the rectum. Primary cytoplasmia was present in both of these lesions. The nuclei and nucleoli were small, and the average nucleonucleolar ratio was about twice as large as the ratio in carcinoma. In a benign polyp in which there was primary cytoplasmia the measurements were very much like those of the inflammatory lesions. The results of biometric studies of the rectum were slightly different from the results of similar studies of other organs. In grade 2 carcinoma, the average area of the nucleoli was 0.1 square micron less than it was in grade 1 carcinoma. However, in comparison with the average area of nucleoli in grade 3 carcinoma, that of nucleoli in grade 4 carcinoma was increased markedly; in fact, in each of these grades of carcinoma the average area of the nucleoli was almost twice as great as it was in the next lower grade. In all grades of carcinoma the nucleonucleolar ratio decreased as the grade of malignancy increased, but in grade 3 carcinoma and in grade 4 carcinoma the difference in the ratio was very slight.

Ovary.—In nonmalignant lesions of the ovary the average areas of the nuclei and nucleoli were 41.0 and 2.0 square microns, respectively, and the average nucleonucleolar ratio was 20.5:1. In carcinoma the average areas of the nuclei and nucleoli were 48.7 and 4.0 square microns, respectively, and the aver-

TABLE VI

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE OVARY

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO		
		NUCLEI			NUCLEOLI			SMALLEST	LARGEST	AVERAGE
		SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE			
1	2	25.4	32.0	28.7	1.9	2.3	2.1	12.9:1	13.9:1	13.4:1
2	3	41.0	80.3	58.4	2.5	7.5	4.7	10.7:1	15.8:1	13.4:1

4	0						4.0			12.3:1
	8			48.7						

age nucleonucleolar ratio was 12.3:1 (Table VI). The size of the cells of the membrana granulosa of a Graafian follicle is shown in Fig. 7. In the theca interna of a Graafian follicle the nuclei were very large and the nucleoli also were large; the nucleonucleolar ratio was almost twice as large as it was in carcinoma. In one ovary the average area of the nucleoli of the membrana granulosa was slightly less than the average area of the nucleoli of the theca interna, but the average area of the nuclei of the membrana granulosa was about half as large as the average area of the nuclei in the theca interna. The average nucleonucleolar ratio in the membrana granulosa therefore was low. It was not much higher than the average ratio in carcinoma (14.0:1 and 12.3:1) and was lower than the

Fig. 7.—Membrana granulosa of a Graafian follicle ($\times 1,000$).

ratio in certain specimens of carcinoma. In the corpus luteum the measurements were similar to those obtained for the theca interna; however, in the corpus luteum the average area of the nuclei and, therefore, the average nucleonucleolar ratio, were somewhat lower than they were in the theca interna. In a benign papillary cyst the average areas of the nuclei and nucleoli were very small, and the average nucleonucleolar ratio was about three times as large as it was in carcinoma. In carcinoma of the ovary (Table VI) the measurements were not entirely in agreement with the measurements obtained in specimens of carcinoma of other organs, but the differences were not very marked. As was the case in carcinoma of other organs, there was no relation between the average area of the nuclei and the grade of carcinoma.

Endometrium.—In benign lesions of the endometrium the average areas of the nuclei and nucleoli were 30.68 and 0.84 square microns, respectively, and the average nucleonucleolar ratio was 36.5:1. In carcinoma the average areas of the nuclei and nucleoli were 55.5 and 4.7 square microns, respectively, and the average nucleonucleolar ratio was 13.4:1 (Table VII). Normal endometrial tissue had small nuclei, very small nucleoli, and a very high nucleonucleolar ratio. In inflammatory lesions in which there was primary cytoplasmia the meas-

TABLE VIII

AREAS OF NUCLEI AND NUCLEOLI AND THE NUCLEONUCLEOLAR RATIO IN DIFFERENT GRADES OF CARCINOMA OF THE ENDOMETRIUM

GRADE OF CARCINOMA	CASES	AREA, SQUARE MICRONS						NUCLEONUCLEOLAR RATIO		
		NUCLEI			NUCLEOLI					
		SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE	SMALLEST	LARGEST	AVERAGE

2	6	45.2	63.0	52.4	3.1	4.1	3.4	11.8:1	17.8:1	15.1:1
3	1			51.5			4.5			11.4:1
4	1			72.6			8.2			8.8:1
	14			55.5			4.7			13.4:1

urements approximated those obtained for normal endometrial tissue; the nuclei and nucleoli were smaller, but the nucleonucleolar ratio was slightly higher. In a polypoid endometrium the nuclei also were smaller than they were in normal endometrial tissue, but the average area of the nucleoli was larger than it was in the normal endometrium. The average nucleonucleolar ratio, therefore, was much smaller than the ratio in the normal endometrium, but it was more than twice as large as the average ratio in carcinoma. In a benign polyp the measurements were similar to those obtained for the normal endometrium, but the average nucleonucleolar ratio was a little lower. The number of carcinomas of the endometrium was very small; only one carcinoma was classified in each of the two highest grades of malignancy (grades 3 and 4). However, the results of the biometric studies were similar to the results obtained in the study of other organs; the average area of the nucleoli gradually increased, and the nucleonucleolar ratio decreased as the grade of malignancy increased.

Uterine Cervix.—In nonmalignant lesions of the uterine cervix the average areas of the nuclei and nucleoli were 30.97 and 0.78 microns, respectively, and the nucleonucleolar ratio was 32.7:1. In carcinoma the average areas of the nuclei and nucleoli were 63.7 and 7.0 square microns, respectively, and the average nucleonucleolar ratio was 10.1:1 (Table VIII). Biometric studies of inflammatory lesions revealed that the average areas of the nuclei and nucleoli were large, and the average nucleonucleolar ratio was more than three times as large as it

TABLE VIII

	9			63.7			7.0			10.1:1

was in carcinoma. In a benign polyp the nuelei were large but the nucleoli were small; the nucleonucleolar ratio was about as large as it was in normal tissue. In the biometric studies of carcinoma of the cervix the results were entirely different from the results of similar studies of carcinoma of other organs.

COMMENT

In carcinoma of practically every organ there was some overlapping of the areas of the nucleoli and the nucleonucleolar ratios. However, the overlapping usually was seen between grades 1 and 2, 2 and 3, or 3 and 4; it very rarely was noted between grades 1 and 3, 1 and 4, or 2 and 4.

A careful examination of the results and the tables seems to leave no doubt that, in general, no matter what organ is considered, the average areas of the nucleoli in relation to those of the nuelei are absolutely and relatively much larger in carcinomas than they are in benign lesions. According to this, the average nucleonucleolar ratios are much smaller in carcinoma than they are in benign lesions.

There were few individual specimens of nonmalignant lesions in which the nucleonucleolar ratio was almost as low or even as low as it was in carcinoma. This happened in inflammatory lesions and in benign tumors in which there was secondary cytoplasmia. It is known how frequently certain benign tumors and chronic ulcers become malignant; the ulcers and tumors that become malignant probably are those that are associated with secondary cytoplasmia. In the edges of chronic gastric ulcers and in some of the acini of benign epithelial tumors, the cells of secondary cytoplasmia repeatedly have been seen passing through the basal membrane and invading the tissues in an area that histologically looked perfectly benign and had been previously diagnosed as such. The reverse is also true, particularly in carcinoma of the stomach. In the transitional zone of the mucosa where the growth stops and the normal or inflammatory mucosa begins, the mucosa looks histologically normal for a more or less long distance. However, in the same zone the microscopic examination with an oil-immersion objective shows that the acini are filled with cells of secondary cytoplasmia, and occasionally that one or more acini are broken. This permits the cells to pass into the stroma. The nucleonucleolar ratio of the cells of secondary cytoplasmia in this transitional zone is practically the same as it is in the carcinoma near by.³³ The cells of secondary cytoplasmia probably are cancer cells which have not yet invaded the stroma for some unknown reason. MacCarty,²⁶ Broders,⁴ Raaf,³⁷ and others have expressed the same opinion. Broders⁴ went so far as to consider the cells of secondary cytoplasmia as cancer cells within the tubules or acini. Other cells in which the nucleonucleolar ratios approximate the ratios in carcinoma are those of the membrana granulosa of the ovary, fetus, normal liver, and exophthalmic goiter. The metabolic activity of the cells of these tissues is well known. In addition, at least in the fetus and exophthalmic goiter, there is no doubt that the cells grow fast and have a great reproductive power. Therefore, it seems logical to admit that the large amount of nucleolar substance and the low nucleonucleolar ratio in the nonmalignant lesions that were studied is somewhat related to the great metabolic activity and possibly also to the rapid growth and cellular division. This is not a new idea; the experimental work on

lower animals of Wace, Ludford, and Sayles seems to prove this. Sayles said: "The amount of nucleolar material present in a cell seems to be an index of the activity of its nucleus both in cell metabolism and in preparation for cell division. Two nucleoli within a single nucleus are the result of an increase in nucleolar substance beyond the amount which can exist within the nucleus as a single droplet." The conclusions of Ludford are also conclusive since he said: "Actively growing cells are characterized by their large nucleoli, and by the fragmentation and division of the same. In the adult, nucleoli of cells undergoing active metabolism are relatively large, those in 'resting condition relatively small.'"

It is generally admitted that cancer cells are metabolically very active and have a great reproductive power. Fischer said that in the cultures of cancer cells there are found ten times as many mitotic figures as in the cultures of normal tissues. Since cultures of cancer cells grow slower than those of normal tissues, he explained this fact by the necessity of the cancer cells to divide quickly and said that many divide at one time in order to compensate for the loss of substance produced by the disintegration of many cancer cells whose life has a short duration as has been proved in growth of carcinomatous tissues "in vitro." According to Broders and others, both metabolic activity and reproductive power of the cells in carcinoma increase from grade 1 to grade 4. On the other hand, in Tables I, II, III, and IV, it may be seen that the average area of the nucleoli increases and the average nucleonucleolar ratio decreases in each grade from grade 1 to grade 4. This seems to prove that in malignant lesions the size of the nucleoli also is in direct relation with the degree of malignancy, or better, the nucleonucleolar ratio is in inverse relation with the degree of malignancy. The results shown in Table V corroborate this opinion. Although there is a slight decrease of the average area of the nucleoli from grade 1 to grade 2, the average nucleonucleolar ratio decreases in every grade from grade 1 to grade 4. The results shown in Table VI are not in agreement with this opinion, but they should not be considered when discussing averages; the number of carcinomas of the ovary in this series was very small. The same should be said for the results shown in Table VII, although these corroborate my opinion. For the same reason, the results shown in Table VIII will not be discussed. Even if this table had included a large series of cases the results should not be considered because most of the carcinomas of the cervix are treated by radium before operation is performed; this alters structures, metabolic cellular activity, and growth.

The following questions might arise: (1) If the amount of nucleolar material increases with the grade of carcinoma, or rather, if the nucleonucleolar ratio decreases according to the grade of carcinoma, how shall the overlapping from grade to grade be explained? (2) Why do certain grade 1 carcinomas, in the same organ have the same nucleonucleolar ratio as some grade 2 carcinomas? (3) In the same organ, why is the nucleonucleolar ratio in grade 2 carcinoma the same as in grade 3 carcinomas, and occasionally even in grade 4 carcinomas? The answers to these questions can be only the following ones: (1) The grading of carcinomas depends to a certain extent upon personal estimation of the pathologist who did the grading. (2) The grading of carcinoma has value for orientation of treatment and prognosis but mainly when considered for a group of cases. For some unknown cause the cells of a grade 2 carcinoma may at any

time become very active and soon behave as a grade 3 or 4 carcinoma. On the contrary the cells of a grade 3 or 4 carcinoma may possibly become inactive, and the tumor thus become quiescent.

The relation of the nucleonucleolar ratio to cellular activity being admitted, the lack of constancy of that ratio that has been found by different authors, or even by the same author on different occasions, in normal and pathologic tissues of the same kind can be understood. Thus, for example, in malignant lesions of the stomach the discrepancy of results found by Haumeder (9:1), Naidu (16:1), and myself (14.9:1) is probably due to the fact that in the series of cases studied by Haumeder there were more carcinomas of a high grade than there were in the series studied by Naidu and myself.

CONCLUSIONS

1. The average areas of the nuclei and nucleoli, and the average nucleonucleolar ratio, are not the same in all normal tissues; they vary, probably, according to the function of the organ, and in the same organ they vary with the metabolic activity.

2. In nonmalignant lesions the average area of the nucleoli is smaller and the average nucleonucleolar ratio is larger than in carcinoma.

3. In the cells of the fetus, normal liver, membrana granulosa of the ovary, and exophthalmic goiter the areas of nucleoli and the nucleonucleolar ratios approximate those found in carcinoma. This is probably attributable to the great metabolic activity of these cells.

4. There is more variation in the extreme areas of the nuclei and nucleoli in carcinoma than there is in nonmalignant lesions.

5. The average area of the nucleoli and the average nucleonucleolar ratio vary according to the degree of malignancy; the former in a direct and the latter in an inverse proportion. In carcinoma the average area of the nucleoli increases and the average nucleonucleolar ratio decreases from grade 1 to grade 2, from grade 2 to 3, and from 3 to grade 4.

6. The increased amount of nucleolar substance in cancer cells is most probably attributable to the great cellular metabolism and cellular division characteristic of those cells.

7. The increasing of nucleolar substance associated with the increasing in the grade of carcinoma is most probably attributable to the increase of cellular metabolism and cellular division from grade 1 to 2, from grade 2 to 3, and from grade 3 to 4.

TOXIC REACTIONS WITH GOLD SALTS IN TREATMENT OF RHEUMATOID ARTHRITIS*

ROBERT M. LINTZ, M.D., NEW YORK, N. Y.

IN ANY disease where new remedies are being introduced at frequent intervals one can be sure that none of the proposed methods has a generally accepted value. This condition has prevailed particularly in the treatment of rheumatoid arthritis where an unusually large number of preparations have been suggested. The typical course for such a "new" treatment, as stated by Hench and others¹ is that it "... rises rather rapidly, reaches its peak in about 3 to 5 years, then falls as adverse reports begin to outnumber the optimistic ones. Finally, use of the treatment in any significant degree dies out after 8 to 10 years." These same authors point out that it is significant that the curve of acceptance of gold salts in the treatment of rheumatoid arthritis is still rising after ten years of use.

Many enthusiastic reports on gold compounds in rheumatoid arthritis have been appearing in the European literature, and recently favorable reports have been made by American workers in this field. One of the earliest American reports is by Phillips,² who employed chrysotherapy in 18 patients, 9 of whom were diagnosed as having rheumatoid arthritis. Phillips was not favorably impressed with the value of gold salts. Shortly after this Oren³ gave his results with gold salts in 100 cases of arthritis. Of the 66 cases of rheumatoid arthritis in his series, 60 "responded well." Key and his co-workers⁴ have reported their results from the arthritis clinic of the Washington University School of Medicine, St. Louis. In 70 cases of rheumatoid arthritis they found gold salts definitely ameliorated the course of the disease in the majority of the patients, regardless of the duration of the disease. Sashin, Spanbock, and Kling⁵ found moderate to marked improvement in 85 per cent of the 80 patients with rheumatoid arthritis who received gold salts. Snyder, Traeger, and Kelly⁶ noted improvement in 48 per cent of the 50 cases of rheumatoid arthritis after chrysotherapy.

Those who have had experience with this form of therapy emphasize that, although we have in chrysotherapy a most effective method for the treatment of rheumatoid arthritis, the use of the gold preparations is not entirely without danger. Hartfall, Garland, and Goldie⁷ reported toxic reactions in 41.9 per cent of 900 patients treated with gold compounds. They had 7 deaths—a mortality rate of 0.78 per cent—definitely attributable to gold salts. Sixty-three per cent of the patients treated by Key⁴ had some form of reaction. Crosby⁸ has compared this group of reactions to the accidents that occurred in the early days of organic arsenical drugs.

*From the New York Hospital, the Second (Cornell) Medical Division, Bellevue Hospital, and the Department of Medicine of Cornell University Medical College.

Received for publication, June 24, 1940.

Chrysotherapy is constantly becoming more popular, and pharmaceutical houses are preparing advertising campaigns to acquaint physicians with the merits of their preparations. In view of the widespread interest that is being created by this type of treatment, it is of utmost importance that the physician recognize the different types of reaction to the drug and that the accumulated experience of previous workers be utilized in forming a basic plan of treatment. We have followed more than 100 clinic and private patients treated with gold compounds during the past two years, and it is on our experience with this group that this report is based.

SKIN REACTIONS

The most common toxic reactions due to gold preparations are those occurring in the skin. Pruritus is very frequent after chrysotherapy; it may be generalized or it may involve one or more localized parts of the body. Erythema, often accompanied by pruritus, is also a frequent complication. This, too, may be local or generalized in its distribution. One often encounters a lesion resembling lichen planus. There may be only one or two such areas, or there may be numerous patches scattered over the body. The lesions vary in size from a few millimeters in diameter to a patch having a dimension of 3 or 4 cm. In a few instances urticaria occurs.

Occasionally a patient will develop exfoliative dermatitis. This is always a serious complication; when the process is widespread, the patients are very susceptible to pneumonia.

The pruritus, erythema, and urticaria reactions generally clear shortly after stopping the gold compounds. The lesions resembling lichen planus not infrequently persist and spread for a period of several months after discontinuing therapy. The seriousness of exfoliative dermatitis seems to be in proportion to the extent of the lesion, and the treatment is the same as that of a similar lesion due to an arsenical or other agent. One of our patients developed a complete glove-like desquamation of the skin of both hands and recovered without the aid of any particular therapy.

LESIONS OF THE MOUTH

Second only to skin lesions in frequency are the reactions that occur in the mouth. The usual mouth involvement is a soreness that is noted especially in the tongue; at times the patient will complain of numbness of the tongue. Examination of the mouth at this time reveals no unusual findings. In other instances an ulcerative stomatitis occurs. This is very painful when the patient takes food. Occasionally there are small ulcerations of the buccal mucous membranes. After stopping therapy, the duration of mouth lesions is roughly in proportion to the severity of the involvement, the ulcerations persisting as long as two or three months.

GASTROINTESTINAL LESIONS

Disturbances of the gastrointestinal tract have been seen fairly often by some workers, but in our experience we have not found it a frequent complication of gold therapy. The patient who has a reaction involving the gastrointestinal tract will complain of cramps, nausea or vomiting, or diarrhea. These

symptoms may be mild or severe and may occur alone or in combination. Reactions of this type will clear promptly after the gold salts are stopped.

HEPATIC LESIONS

Jaundice of a benign type is seen at times. It is probably due to a toxic hepatitis and is very apt to run a lengthy course. Several fatal cases of acute yellow atrophy of the liver have been mentioned by others,⁸ but this type of reaction is very rare.

RENAL LESIONS

A mild albuminuria is a very frequent complication and is no indication for stopping the medication. Hematuria or a marked degree of albuminuria will disappear shortly after discontinuing treatment.

VASOMOTOR REACTIONS*

In almost every case the patient will experience a flushing of the face within one or two minutes after receiving the gold compound. The face appears fiery red, and the patient complains of a feeling of unusual warmth, often accompanied by a sensation of giddiness and vertigo. This reaction generally passes away in three or four minutes and leaves no aftereffect. One of our patients had such a reaction occurring about eight hours after he received the gold preparation. In another instance the vasomotor reaction became more severe with each subsequent treatment and the patient eventually had an attack of syncope. The patient collapsed and for several seconds the radial pulse could not be made out and the heart sounds were not audible. Stimulants were used and as the heart action resumed showers of ectopic beats were made out; in an hour's time the regular sinus rhythm was restored.

LOCAL REACTIONS

A large number of patients complain some time in the first two to six weeks of treatment that their arthritis is very much worse. Examination at this time will reveal that there has been a flare-up in joints in which the arthritis has been dormant and that there has been an increase of pain in the joints showing an active arthritis. Most of the patients experiencing this sort of reaction are likely to show a very satisfactory improvement with continued gold salt therapy. At times the exacerbation of joint symptoms will be accompanied by a rise of temperature to 102° or 103° F. In a few cases the temperature rise has occurred with no indication of joint or other reaction.

BLOOD DYSCRASIAS

It is in this group of reactions that fatalities are most likely to occur. Fortunately, reactions of this type are very infrequent. Cases of thrombocytopenic purpura, agranulocytosis, and aplastic anemia have been described, and in several instances a fatal outcome has resulted.

TIME OF ONSET OF REACTIONS

Except for the vasomotor disturbances it is impossible to predict the time of occurrence of reactions. Any of the reactions that have been described can oc-

*This type of reaction occurred principally with myochryslne. Recent change in the method of producing the preparation has practically eliminated this vasomotor effect.

cur after the first full dose of gold. Frequently a reaction will occur midway in a course of treatment. Many toxic reactions have occurred at a considerable time after the cessation of chrysotherapy. Reznikoff⁹ treated a young nurse for aplastic anemia five years after she had received gold salts for lupus vulgaris. It is the unpredictable nature of these reactions that constitutes the chief hazard in the use of gold salts in rheumatoid arthritis.

PREVENTION AND TREATMENT OF REACTIONS

Were it possible to prevent or minimize the reactions to gold salts we would have a potent remedy that could be employed easily by any physician. In an early paper in which they report on their first 100 cases of rheumatoid arthritis treated with gold salts, a statement made by Hartfall and Garland¹⁰ is still most pertinent: "Chrysotherapy should only be undertaken by those who are fully alive to its dangers. The patient should be warned of these possibilities."

Skin tests and patch tests have been of no value in indicating those who might have reactions. The simultaneous parental administration of sodium thiosulfate or of calcium preparations has not reduced the incidence of reactions. At times it has seemed that an increased vitamin C intake, such as can be obtained from the daily intake of several glasses of orange or tomato juice, lowered the number of reactions, but this has not been confirmed.

The reactions are treated by a method identical to that employed in similar lesions due to any other cause or factor. Nicotinic acid has been considered helpful by some in the treatment of the minor reactions; others have favored cevitamic acid; neither seems to alter the course of reactions to any significant degree. In exfoliative dermatitis sodium thiosulfate and calcium salts are recommended empirically.

CONTRAINDICATIONS

The only definite contraindications to the institution of gold salt therapy are blood dyscrasias and diseases of the kidneys or liver. Patients with hepatic or renal involvement, or who have had serious disturbance of the hematopoietic system are poor risks for this form of therapy. Gold compounds should be used with extreme caution in patients who give a personal or familial history of allergy. Treatment should be stopped at the first sign of any reaction, regardless of how trivial it may seem. When skin lesions, lesions of the mouth, gastrointestinal disturbances, and the less severe renal lesions have completely disappeared, treatment may be resumed. If any other type of reaction should occur, it is not advisable to resume gold therapy.

The presence of essential hypertension or of arteriosclerosis is no contraindication to this method of treatment.

CHOICE OF PREPARATIONS

There are several preparations of gold salts on the market; these differ in composition of the salt but all have in common the presence of a sulfur radical in the compound. There is a considerable difference of opinion in regard to variation in toxicity of the different preparations. Some of the patients who have toxic reactions appear to have an idiosyncrasy to gold and react to the first dose or to very small doses. Others seem to require a certain amount of

the gold salts before they have a similar reaction. In this latter group the problem arises whether it is safer to employ any particular compound.

We have preferred a watery solution of gold sodium thiomalate (myochrysin) given intragluteally. With this preparation we have had the usual minor toxic reactions and occasionally one of the more severe type. There have been no fatalities in this group. Gold sodium thiomalate is being used satisfactorily by many who are employing chrysotherapy.

In a very small series of patients who received gold sodium thiosulfate in our arthritis clinic at Bellevue Hospital, there have been two with very severe reactions, one of whom died. One of these patients developed an exfoliative dermatitis after receiving an initial dose of 0.05 Gm. of gold sodium thiosulfate intravenously, followed by 8 injections of 0.1 Gm. at weekly intervals—a total of 0.85 Gm. of the drug. She was admitted to the hospital and subsequently developed a lobular pneumonia which proved fatal. Additional autopsy findings consisted of acute colitis and parenchymatous degeneration of heart, liver, and kidneys. The other patient received 10 intravenous injections of gold sodium thiosulfate in the same manner, or a total of 0.95 Gm. of the drug in ten weeks. Within a few days she developed large patches resembling lichen planus that covered the arms, face, and chest. Shortly after the appearance of the skin lesions large purpuric areas appeared on the feet. Eight months after the onset of these lesions the only change seemed to be an increase in the areas of the purpura. At this time her blood platelet count was reduced to 40,000 per cubic millimeter. It would seem that the intravenous use of gold sodium thiosulfate is definitely attended with increased risk.*

PLAN OF USE

Before starting chrysotherapy the patient should have a thorough physical examination. Laboratory work should consist at least of a complete blood count, blood platelet count, red blood cell sedimentation rate, and urinalysis. As already indicated, our choice of preparations is a watery solution of gold sodium thiomalate (myochrysin). This preparation is given into the gluteal muscles at weekly intervals. The initial dose should consist of 0.01 Gm. of the salt (which contains 50 per cent gold), followed by 0.025 Gm., 0.05 Gm., and 0.1 Gm. thereafter until a total of 1.0 Gm. is given. The laboratory determinations mentioned above must be repeated at intervals not exceeding four weeks. With the appearance of any significant change (except in red blood cell sedimentation rate) the determinations should be done weekly and the gold stopped if an unsatisfactory trend appears. Frequently a return of the red blood cell sedimentation rate toward normal coincides with the clinical improvement of the patient. At other times a patient may feel much better, but the red blood cell sedimentation rate will not change. At the end of a course the patient is given a rest period of six to eight weeks. If there has been no improvement in the condition, a second, and even a third, course should be given, observing the usual precautions. Should there be marked improvement by the end of the first or second course, it is generally advisable for the patient to receive another full course after a proper rest interval.

*In a subsequent series of cases where the maximum single dose of gold sodium thiosulfate was 0.05 Gm., excellent clinical results were obtained with a minimum of minor toxic reactions.

SUMMARY

In gold salts we have a valuable drug for the treatment of rheumatoid arthritis. The use of this preparation is attended with certain risks, and the physician must be able to recognize the first manifestation of any toxic reaction. These reactions, which may occur as exacerbation of joint symptoms or as lesions of the skin, mouth, gastrointestinal tract, liver, kidneys, vasomotor apparatus, or hematopoietic system, have been described. Fatalities have been reported with the use of gold compounds subsequent to the development of exfoliative dermatitis, acute yellow atrophy of the liver, and the blood dyscrasias. It is not possible to predict the time of occurrence of reactions since they may appear any time between the first injection and a time several months after the cessation of chrysotherapy. Suggested methods of preventing and controlling reactions have not proved successful. Chrysotherapy is contraindicated in patients with involvement of liver or kidneys or the hematopoietic system and should be used with caution in those having a history of allergy. Treatment should be discontinued at the first sign of any toxic reaction and may be resumed when the signs have cleared, except in those patients who develop exfoliative dermatitis, blood dyscrasias, or severe hepatic or renal lesions.

The preparation we prefer is a watery solution of gold sodium thiomalate (myochrysin) given intragluteally in doses no larger than 0.1 Gm. at weekly intervals until a total of 1.0 Gm. has been administered. Following a rest period of six to eight weeks a second, or even a third, course is given as indicated. To properly safeguard the patient, it is essential that in addition to a thorough physical examination certain laboratory procedures be done before starting gold salt therapy. These determinations should consist of a complete blood count, blood platelet count, red blood cell sedimentation time, and urinalysis. This laboratory work should be repeated at least every four weeks, and with the appearance of any unfavorable change the determinations should be done weekly. Treatment should be discontinued if an unsatisfactory trend appears.

CLINICAL CHEMISTRY

THE CHEMISTRY OF INFECTIOUS DISEASES*

II. CYSTINE CONTENT OF THE HYDROLYSATES OF BLOOD SERA IN EXPERIMENTAL PNEUMONIA IN DOGS

M. L. CROSSLEY, PH.D., BRUNO VASSEL, PH.D., AND G. L. CHRISTOPHER, PH.D.
STAMFORD, CONN.

BRDICKA¹ interpreted the decrease in the height of the polarographic waves of cancerous sera as being due to less cystine, i.e., cystine plus cysteine. Applying the Heyrovsky polarograph to the study of whole sera of type I pneumococcus infected dogs, we observed that the height of the catalytic protein wave also decreased with an increase in the severity of infection, and returned to normal upon recovery of the animal.² Brdicka¹ believed that the height of the polarographic double wave of serum in cobaltic ammonium buffer is a measure of the amounts of available sulfhydryl and disulfide groups of the serum proteins, while nonproteic sulfhydryl and disulfide groups (i.e., free cysteine and cystine) in trivalent cobalt buffer are without influence² on the height of the wave. Consequently, a decrease in the wave height of whole serum with pneumococcal infection would indicate a diminution of peptide cystine. To ascertain the correctness of this deduction, the cystine content of the acid hydrolysates of dog sera before and after pneumococcal infection was determined.

EXPERIMENTAL

The care of the dogs and the production of experimental pneumonia according to the procedure of Terrell, Robertson, and Coggeshall^{3†} were described in a previous report.²

Samples of 0.4 ml. of serum were refluxed with 2.5 ml. of the formic acid-hydrochloric acid mixture of Miller and du Vigneand⁴ in an all-glass apparatus in an oil bath at 110 to 120° C. for eighteen hours. After dilution with 5 N hydrochloric acid to 10 ml., cystine was determined on 1 ml. aliquots in triplicate by the method of Vassel,⁵ care being taken to prepare the standard cystine curve from a cystine solution of identical formic acid and hydrochloric acid composition and of the same normality (average 7 N) as that of the hydrolysates. For the polarographic analyses 1 ml. of the hydrolysate was diluted with water to

*From the Research Laboratories of the American Cyanamid Co., Stamford, Conn., and the Calco Chemical Division, Bound Brook, N. J.

A report of this work was presented at the One Hundredth Meeting of the American Chemical Society, Detroit, Mich., September 9 to 13, 1940.

Received for publication, February 13, 1941.

†Culture furnished through the courtesy of Dr. O. H. Robertson, of the University of Chicago.

4 ml., and 0.5 ml. of this solution was added to a cobaltous ammonium buffer of the following composition:

To 2 ml. of an 0.008 N cobaltous chloride solution was added 1 ml. of 1 N ammonium chloride, followed by 1 ml. of 1 N ammonium hydroxide and 5.5 ml. of water. The mixture was then electrolyzed with the galvanometer set at $\frac{1}{100}$ sensitivity.

The polarographic cystine values were at first determined by the procedure of Stern, Beach, and Maey.⁶ This led to results which were found to be uniformly 15 to 25 per cent lower than those obtained by the colorimetric method. When a standard curve was prepared by plotting the increase in wave height of the catalytic wave against increasing amounts of pure cystine in acid solutions of identical composition and normality with those of the hydrolysates, a calibration curve was obtained which when used on the serum hydrolysates gave cystine values which were within ± 5 per cent numerically the same as those

Fig. 1.—The depressing effect of arginine and histidine on the polarographic wave height of cystine in cobaltous ammonia buffer.

obtained by the procedure of Stern and others,⁶ and which were uniformly lower than those obtained by colorimetry. However, since the solution used in preparing the calibration curves contained no other amino acids than cystine, this agreement seemed surprising, for Sládek and Lipschuetz⁷ state that the presence of arginine and histidine depress the wave height of cystine polarograms. We found that the addition of these and other amino acids in amounts similar to those found in serum⁸ did not depress the wave height when added separately or together to 0.015 mg. of cystine. The following amino acids were tested in this manner: 0.17 mg. of arginine, 0.004 mg. of histidine, 0.02 mg. of tyrosine, 0.004 mg. of tryptophane, and 0.027 mg. of glutamic acid. If the amounts of arginine and histidine are increased, however, then both amino acids depress the wave height, histidine exerting a greater effect, mol for mol, than arginine. This is shown in Fig. 1, where curve I is the polarogram of 5.42×10^{-5}

mols of cystine in cobaltous ammonium buffer. The addition of 3.86×10^{-6} mols of arginine (curve II) or 0.194×10^{-6} mols of histidine (curve IV) will depress the current-voltage wave of 5.42×10^{-8} mols of cystine by 18 per cent, while 10.6×10^{-6} mols of arginine depress it 39 per cent (curve III) and 1.94×10^{-6} mols of histidine 43.5 per cent (curve V). The presence of appreciable amounts of histamine will also influence the cystine wave height. Histamine in cobaltous ammonium chloride buffer shows a maximum of its own at -1.75 volts. Since the maximum produced by cystine occurs at -1.65 volts, the presence of histamine increases the wave height of the cystine polarogram.

The procedure of Stern and associates⁶ is much more time-consuming than the use of a standard cystine curve without, apparently, gaining in accuracy. The majority of the cystine values reported here were, therefore, calculated from a cystine calibration curve, i.e., the wave height produced by pure cystine solutions were compared to that given by the hydrolysate.

Fig. 2.—Curves I to IV. Cystine content of the serum of normal Dog XI two hours after a meal (I—colorimetric, III—polarographic) and twenty hours after a meal (II—colorimetric, IV—polarographic). Curve V—variations in cystine content of Dog XII after infection with type I pneumococcus.

RESULTS AND CONCLUSIONS

The normal variations in the cystine content of serum hydrolysates of the same dog are plotted in Fig. 2, where curves I and III represent colorimetric and polarographic cystine determinations of the blood of the same dog drawn on different days after about twenty hours of fasting. Curves II and VI represent the corresponding cystine curves two hours after feeding. Although the colorimetric and polarographic determinations vary in absolute values, the graphs of the analyses by the two methods run fairly parallel to each other. They also show that the tendency to fluctuate is independent of the time of day at which the blood was drawn and of whether or not the animal had been given food recently. These normal variations were of the same magnitude as those previ-

Fig. 3.—Variations in the cystine content of the serum hydrolysates of 3 dogs after infection with type I pneumococcus. Curve A—analysis by a colorimetric method; curve B—analysis by the polarographic method.

ously observed when the fluctuations of the whole sera of normal dogs were analyzed polarographically in cobaltic ammonium chloride buffer.² The lowest normal cystine value of the eight dogs is 300 and 200 mg. per cent for the colorimetric and polarographic methods, respectively, while maximum values for the two procedures were 420 and 260 mg. per cent. The maximum fluctuation of an individual dog amounted to about ± 15 per cent of the average normal value in either of the two methods, this tendency being directed more toward higher than toward lower values. It was noticed, furthermore, that the serum hydrolysates from normal puppies always contained appreciably less cystine per 100 ml. of serum than those of older animals.

During the first twenty to sixty hours after infection with type I pneumococcus, corresponding to the spreading of the infection in the lung as shown by x-ray, a sharp drop of 15 to 30 per cent of the former average cystine value of the dog serum occurred. The sudden decrease was not continuous but fluctuated, showing a strong downward tendency, this being opposite to the normal tendency.

Fig 1.—Variations in cystine content (I), body temperature (II), and total solids (III) of the serum of Dog 1 after infection with type I pneumococcus.

In Fig. 3 serum cystine concentrations were plotted against time after infection for three representative cases of the eight dogs studied. The results of the colorimetric analyses are designated curves A, while curves B represent always the corresponding polarographic values. It can be seen that after the lowest concentrations were reached, the cystine values returned during the next one hundred to two hundred hours after infection to their previous normal levels, even exceeding them at times, as if by a compensatory mechanism. During this period the x-rays show that resolution of the infected area of the lungs is taking place.

From the three hundredth to the six hundredth hour after infection, corresponding to the time of recovery as measured by the polarographic peptone wave³ and by the completed resolution of the lungs, the cystine content of the serum returned to its normal level. The graph of Dog XII is of special interest,

Fig. 5.—Cystine (I) and nitrogen (II) content of the sera of 3 dogs after infection with type I pneumococcus.

inasmuch as this animal died at the two hundred and fiftieth hour after infection (Fig. 2, curve V). A rather steady decrease from a normal level of 340 mg. per cent to a low of 234 mg. per 100 ml. of serum occurred during the illness, the latter value being one of the lowest cystine levels found (colorimetrically) in this study.

A comparison of the cystine concentrations of the serum hydrolysates during infection (Fig. 4, curve I) with the body temperature (Fig. 4, curve II) and with the solid contents of the serum of the same dog (Fig. 4, curve III) is very interesting. While the parallelism is not absolute, there is a tendency for the cystine level to decrease with a fall in total solids, preceded by an increase in body temperature. The first indication of pathologic symptoms is always reflected first in changes of the body temperature, while the changes in total solid and cystine values lag by seven to twenty-four hours. The low body temperatures observed during the first ten hours after infection are produced by the injection of morphine sulfate which is used to lower the resistance of the body to the invasion of the pneumococci. The drop in the serum solids reaches a maximum of 8 to 10 per cent below the normal level, while the maximum decrease in cystine concentration is from 20 to 30 per cent. In an attempt to explain this observation the total and nonprotein nitrogen values were studied in a few of the dogs. The latter decreased during infection from 50-55 to 30-45 mg. per cent, while the former fell from a normal level of 1,000-1,150 to 800-950 mg. per cent. In Fig. 5 the decrease in total nitrogen, as well as the corresponding decrease in cystine, is plotted against time after infection for Dogs I, IV, and VI. It is evident that the nitrogen and cystine curves run fairly parallel to each other. Occasional sudden and large deviations from this parallelism, especially noticeable in the case of Dog VI, cannot be explained. The maximum decrease in nitrogen amounts to 20-25 per cent, which approximates very closely the percentage drop in cystine.

Thus, during infection the observed fall in the cystine values of the serum hydrolysates are closely related to the corresponding lowering of the total nitrogen of the serum, undoubtedly representing changes in serum protein concentration. The previously observed fall in the height of the polarograms of whole dog sera with pneumococcal infection² must, therefore, be attributed also to a decrease in proteic cystine.

SUMMARY

The cystine content of the hydrolysates of dog sera after infection with type I pneumococcus was determined. Parallel analyses were made with colorimetric and polarographic analytical methods.

The colorimetric procedure gave uniformly higher values than the polarographic procedure.

Both methods showed that the cystine content of the serum hydrolysates decreased during infection, and returned to normal upon recovery.

The percentage decrease in cystine concentration of the serum hydrolysates was paralleled by the percentage fall in their total nitrogen content. This suggested that a fall in the protein level occurred during infection.

We gratefully acknowledge the invaluable help and the unstinted cooperation which we received in this study from Dr. W. Harry Feinstone of this laboratory. Dr. Feinstone, while actively studying related phases of pneumococcal infection in dogs, kindly took over the culturing of the pneumococci and the actual infection of the dogs, and followed the progress of the disease systematically with x-ray photographs.

EFFECT OF DESOXYCORTICOSTERONE ACETATE ON HYPOCHLOREMIA IN PNEUMONIA*

ROBERT A. NEWBURGER, M.D., NEW YORK, N. Y.

THE present study was undertaken to determine what effect, if any, desoxycorticosterone acetate has upon the hypochloremia so frequently found in patients with pneumonia.

McLean¹ in 1915 observed that chloride is treated by the kidneys as a threshold substance and that the threshold is decreased in pneumonia. Following crisis, the threshold rises and chlorides are retained until normal serum levels are reached. The presence of a lowered renal threshold hardly provides a complete explanation for the hypochloremia; however, since desoxycorticosterone acetate, among its other effects, produces a rise in the renal threshold for chloride in Addison's disease, it was thought possible that this would result in a rise in the chloride, which might be beneficial in patients with pneumonia.

MATERIAL

For the purpose of the experiment there were selected 4 patients acutely ill with lobar pneumonia of two to five days' duration who had serum chloride concentrations of 95.1 milliequivalents per liter, or less. Detailed balance

*From the Department of Chemistry, New York University College of Medicine.
Received for publication, January 15, 1941.

studies were not made. The effect of desoxyeorticosterone acetate was determined by following the chloride and carbon dioxide contents of the serum. All patients were given 6 Gm. daily of sodium chloride (Lilly's Enseals). The diets were liquid or soft, without added salt except that taken as desired by the patients from weighed salt shakers. Chlorides were determined by the method of Patterson,² and the carbon dioxide content by the method of Van Slyke and Neill.³

The dosage of desoxyeorticosterone used was between 10 and 20 mg. per day (in the form of a solution in sesame oil, given intramuscularly). The results of treatment in the 4 patients are summarized in Table I.

TABLE I

CASE	DAY	NaCl INTAKE* (GM.)	DOCA† (MG.)	SERUM CHLORIDE MEQ./L.	CL + CO ₂ MEQ./L.

	3		0	104	132

*In addition to amount in "salt-free" diet.

†Desoxyeorticosterone acetate.

‡Plus 10 c.c. Cortin (Upjohn) intravenously.

RESULTS

Daily 10 mg. doses of desoxyeorticosterone acetate did not appear to raise significantly either the serum chloride level or the sum of the carbon dioxide and chloride levels in pneumonia patients who were given not less than 6 Gm. of salt a day. In Case 3 where larger doses of the hormone were given, there was a moderate and steady rise in the serum chlorides, but as striking a rise took place in Case 4 where no desoxyeorticosterone acetate was given.

Clinically, there was no difference to be noted between patients receiving desoxyeorticosterone acetate and those who did not, nor did the chloride levels, either initially or after treatment, seem to parallel in any way the clinical state of the patients. All 4 patients were under treatment with sulfonamide derivatives.

These findings are similar to those reported by Winkler and Crankshaw⁴ who were unable to raise the serum chloride and sodium concentrations substantially by the administration of salt and potent cortical hormone in a number of patients with hypochloremia accompanying tuberculosis, carcinoma of the lung, and arteriosclerotic heart disease.

SUMMARY AND CONCLUSIONS

Of 4 patients with lobar pneumonia who had low serum chloride levels, 3 were treated with desoxycorticosterone acetate, while one received salt alone. Ten milligrams daily of desoxycorticosterone acetate had no effect, and 15 to 20 mg. had a very doubtful effect upon the serum chloride. Clinically, there seemed to be no benefit to pneumonia patients treated with desoxycorticosterone acetate in the dosages administered.

BLOOD SERUM CALCIUM IN THE NEGRO*

HAROLD D. WEST, PH.D., AND NELSON C. JEFFERSON
NASHVILLE, TENN.

THE paucity of data in the literature on the serum calcium content of the blood of Negroes in the United States and environs constitutes a gap in our knowledge which bridged might be of value in explaining racial differences in susceptibility and response to treatment in certain diseases. The following report represents a study designed to establish a normal value for blood calcium in this group.

EXPERIMENTAL

A total of 385 determinations on blood serum calcium of 309 normal persons were carried out. All of them were American or foreign-born Negroes, representing thirty-two states, the District of Columbia, the Virgin Islands, and four foreign countries. The subjects were students, professors, instructors, technicians, secretaries, and janitors from the medical school, the George W. Hubbard Hospital, and a group of subjects including six children from a WPA Youth Center in Nashville.

Blood was collected in the postabsorptive state. Samples were received in 15 c.c. centrifuge tubes with careful handling in order that the erythrocytes might not be injured and a hemolytic serum be produced. The blood was allowed to clot, and the material was subjected to centrifugation for more com-

*From the Department of Biochemistry, Meharry Medical College, Nashville.
This work was supported by a grant from the John and Mary R. Markle Foundation. A preliminary report was presented at the annual meeting of the Volunteer State Medical Society in June, 1940.

plete separation of the serum and the clot. Tubes were stoppered during centrifugation—loss of water through evaporation being sufficiently appreciable to give high values for the calcium.

Analyses were carried out according to the Clark-Collip modification of the Kramer-Tisdall procedure,² and all determinations were done in duplicate. If any red blood cells or hemoglobin were present following precipitation of

TABLE I
BLOOD SERUM CALCIUM IN NORMAL SUBJECTS

SUBJECTS	NUMBER	RANGE	MEAN	STANDARD DEVIATION
Normals	385	9.03-11.86	10.39	0.65
Male				
Adults	341	9.03-11.86	10.41	0.69
Female				
Adults	38	9.53-11.05	10.24	0.46
Children	6	9.69-11.42	10.30	0.57

calcium as the oxalate, they were removed as completely as possible in the subsequent washings in order that absence of any reducing noncalcium oxalate substances might be assured. The permanganate titration was carried out in tubes held in a water bath at 70° to 75° C. The criterion for the normal state was based upon the results of a thorough physical examination, including serologic tests executed by a corps of technicians from the medical and hospital staff.

Serum calcium was determined twice on blood from 76 normal subjects—the second samples being taken after an interval of from seven to twelve months.

RESULTS

The results of the experiment are shown in Table I.

DISCUSSION

Unique in the literature on the subject of blood serum calcium in Negroes is a paper¹ in which the conclusion is reached that serum calcium averages 10.93 mg. per 100 c.c.*—a value 0.43 mg. per 100 c.c. higher than the normal blood serum calcium for white persons which is given as 10.50 mg. per 100 c.c. This normal was established on the basis of an average of forty-four determinations. Neither the range of values obtained nor the method used was given. Differences in susceptibility to, and treatment of, tuberculosis in Negroes were explained in part on this basis.

In the present work a larger series was used and the subjects were taken from widely separated areas. The majority of the subjects were students and blood samples were taken shortly after their arrival in Nashville. Values obtained fell within the range of 9.03 to 11.86 mg. per 100 c.c., with a mean of 10.39 mg. per 100 c.c. Since the normal value for blood serum calcium varies from 9.00 to 11.50 mg. per 100 c.c.,³ with a mean value of 10.3,³ it would seem

*In the article cited the values actually given were expressed in grams per 100 c.c. The author could not be reached but it was assumed that these were intended to read milligrams per 100 c.c.

on the basis of the values obtained by us that the blood serum calcium for the group here investigated is of the same order of magnitude as is that of others.

Of interest in this connection are the reports of Radna⁴ who found blood serum calcium in 134 natives of the Belgian Congo to vary from 9.97 to 10.73 mg. per 100 c.c., and of Stone,⁵ who suggested that the normal European range (9.00 to 11.00 mg. per 100 c.c.) for calcium should be adhered to in the interpretation of calcium values of normal Rhodesian natives.

Thanks are due to Mr. T. A. Jones for technical assistance, and to Dr. F. W. Claytor and Dr. J. S. Chandler for obtaining the blood samples. Above all are we grateful to the Dean of the College, Dr. E. L. Turner, without whose interest and cooperation this work would not have been possible.

CONCLUSIONS

1. A total of 385 determinations of blood serum calcium on 309 Negroes were carried out.
2. Blood serum calcium in this group is of the same order of magnitude as is found in other groups of the population.
3. These results are not in accord with those of Harrell.¹
4. Supposed racial differences in susceptibility and response to treatment in tuberculosis cannot be predicated on differences in blood serum calcium.

LABORATORY METHODS

GENERAL

A SIMPLE CONSTANT INJECTION APPARATUS*

H. NECHELES, M.D., PH.D., AND W. H. OLSON, CHICAGO, ILL.

IN OUR laboratory we have developed a practical and efficient apparatus for constant injection which has such advantages that we want to make its details known for the use of other investigators.

Two types of constant injection pumps are most frequently used. First, a syringe, the barrel of which is moved forward mechanically,¹ and second, a pump with valves, by means of which the fluid from a container is aspirated and ejected into the animal. The best known pump of this type is the Woodyatt pump,² and it is a modification of this apparatus that we are reporting here. The rotor type of injection pump avoids the use of valves but is better suited for injection of larger amounts of fluid.

Description of Apparatus.—A 110 volt, 2 amperes, $\frac{1}{20}$ horse power, 60 cycle constant speed motor with 1,125 r.p.m. is employed.† The motor has a built-in reduction gear with a ratio of 40:1. The gear of the motor is connected to a reduction gear box, as shown in Fig. 1. A simple gear shift (*A*), as used by Soskin in the most recent modification of his constant injection pump,¹ permits easy shifting between the seven variable speeds. The transmitting axis of the gear box is connected to a stroke length adjuster which is manipulated by a screw (*B*) and can be set by a wing screw (*C*). The rotating motion of the stroke length adjuster is transformed to horizontal linear motion by *D*, which is

TABLE I

VOLUME EJECTED BY PUMP AT STROKE LENGTH OF 10 MM. AND VARYING SPEEDS

Received for publication, July 18, 1940.

is elamped down tightly. Larger syringes can also be used. The tip of the syringe is connected by pressure tubing to a small T-piece *F*, the ends of which are connected to the valves. All (glass) connections are glass to glass. The valves are constructed in the following manner (Fig. 2): A piece of thick capillary glass tubing is covered on one side by a thin dental rubber dam which is tied to it on a small groove. At the side of the capillary tube a small incision is made into the rubber membrane with a razor blade, and the capillary tube and the glass jacket are connected by means of a piece of heavy rubber tubing. This valve has the advantage of great simplicity, small dead space, no backflow, and practically no elastic back pressure. The intake part of the valvular system dips directly into a beaker containing the fluid to be injected. This makes it easy to change from solution to solution for injection purposes. The outlet

CONSTANT INJECTION PUMP

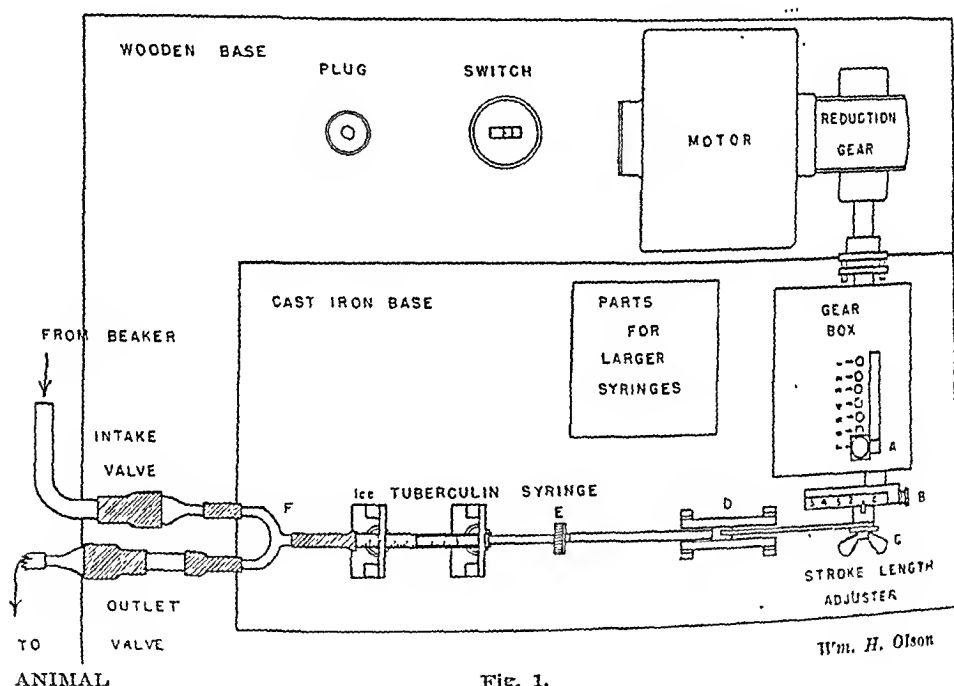

Fig. 1.

valve is connected to the injection cannula in the animal through a thin rubber tube. The volume of fluid in the complete valvular system is 6 c.c. Table I demonstrates results obtained in tests with the assembled instrument. Each number is the average of three determinations, except the last one which was repeated ten times. The tests were extended over a period of three days, with no change in the degree of accuracy of performance. In order to obtain exact results all rubber tube to glass connections must be wired, air bubbles must be eliminated, and the solutions must be gas free. The syringe must be renewed from time to time because the constant motion tends to grind down the piston. The piston must be greased with stopecock grease. As can be seen from Table I there is a nearly linear relationship between the ejected volume of fluid and the number of strokes, degree of gear reduction, and time. The small deviations from an

exact linear relationship are within the limits of error of our readings of the volumes in graduated cylinders. If one does not want to check the pump regularly and rely on previous checks, the volume of injected fluid can be read conveniently from a graduated cylinder into which the intake tube is introduced.

Injection by this pump is not continuous but rhythmic, varying between $1\frac{1}{2}$ and 96 strokes per minute. The volume varies between approximately 0.5 and 30 c.c. per minute, at a stroke length of 10 mm. By reducing the stroke length proportionately smaller amounts and by increasing it, proportionately larger amounts may be injected. The apparatus has been in use in the laboratory for more than two years and has been found satisfactory.

Fig. 2.

SUMMARY

A constant injection pump is described in which speed and stroke are adjustable. Simple and efficient rubber membrane valves are used which do not leak and have a minimum of elasticity to back pressure. The instrument was constructed for us by our mechanic, Mr. Carl Griesmeyer.

A CELLOPHANE STRAW USED AS AN INK-WRITING POINTER IN KYMOGRAPHIC WORK*

EMERICK FRIEDMAN, M.S., M.D., NORWICH, CONN.

IN STUDYING the respiratory pattern of psychiatric patients it was necessary to obtain long, continuous pneumographic tracings. Since this was impractical when carried out by means of the standard smoked-drum technique, an inexpensive ink-writing setup was devised, which not only solved the main problem mentioned above but was rugged enough to withstand sudden psychomotor fluctuations noted in state hospital patients, and, at the same time, eliminated the hazard of fire when recording was done on the regular wards. This ink-writing pneumographic system consists essentially of an ordinary cellophane straw with the tip fashioned and trimmed to resemble a small quill.

Fig. 1.

The entire apparatus is designed as follows: About 2 to 3 cm. of the end of the straw is pressed flat with the fingers and then folded in two lengthwise. A 5 mm. tip, trimmed to a sharp point, is bent at a right angle. This end is dipped into ordinary fountain pen ink to which has been added gum tragacanth

*From the Metropolitan State Hospital, Waltham.
Received for publication, July 9, 1940.

solution, 5 c.c. per 2 ounce bottle. The ink is drawn up by oral suction to a 2 to 3 cm. level in the straw. The other end of the straw is inserted into two celluloid "sights," one glued to the center of the tambour and one on the air pipe behind the tambour, keeping the straw straight and acting as fulcrum. A 3 to 4 cm. length of straw attached to an elongated arm of the signal magnet may serve as an ink-writing time marker. If the motor-driven Harvard kymograph is used, cheap paper may be purchased in large rolls of 6 inch width from any paper mill. This is rolled on the small drum, threaded backward around the other small drum and fastened with tape to the recording drum so that as the tracing is made the paper is automatically wound up. The ink dries by the time the tracing has gone around the drum. With this procedure, long, continuous, ink tracings may be made with the pointer moving in the vertical plane.

FIG. 2.

Fig. 1 illustrates the setup of the cellophane straws on a standard motor-driven Harvard kymograph.

Fig. 2 is an abdominal and thoracic pneumograph of an induced metrazol convulsion. This tracing illustrates the ruggedness and apparent accuracy of this ink-writing straw.

The setup, as described, has given satisfactory ink-written pneumographic tracings as well as records of certain muscular movements for the past year. The lightness of this cellophane straw and the simplicity of the described apparatus, with the elimination of time spent on the smoked-drum technique, should make this a usable setup, especially in student and hospital laboratories.

POSSIBLE SIGNIFICANT ERRORS IN ROUTINE TUBERCULIN TESTS*

NORMAN ROSENBERG, M.D., AND ARTHUR C. ALLEN, M.D.,† NEW YORK, N. Y.

IN A GENERAL hospital the intracutaneous tuberculin test is widely used for diagnostic purposes. The substance usually employed is old tuberculin (O.T.), although in recent years the purified protein derivative (P.P.D.), a highly refined but more expensive tuberculo-protein, has found extensive use.

In the preparation of very dilute solutions of tuberculin for skin tests, there are possible a number of technical errors, some of which have been repeatedly pointed out in the literature. Thus, Parish and O'Brien (1935) have amply demonstrated that the usual cleaning and sterilizing procedures fail to destroy or to remove an appreciable quantity of residual tuberculin from glassware with which this highly tenacious and stable substance was previously in contact. Nelson, Seibert, and Long (1937) have reaffirmed the remarkable heat stability and adherence to glass, and have accordingly advised the use of individual, marked syringes for each dilution.

Most standard textbooks on clinical and laboratory procedure mention no detailed method for diluting old tuberculin, while often discussing minutely the actual method of performing the test itself. In those few manuals that do discuss dilution procedure, a variety of methods is described. A review of the current literature reveals a similar variation in methods suggested for the preparation of dilutions of old tuberculin.

In canvassing a number of large general hospitals, we were again struck with the variety of methods used to prepare solutions of tuberculin. This variation in dilution technique was confined to methods employing old tuberculin. Institutions using purified protein derivative, which is in the form of tablets of known weight, show more uniformity in procedure, thus reflecting the greater ease with which this substance may be handled. The following is a procedure which, according to our information, is likely to be used in some instances:

Dilutions of tuberculin are prepared by drawing up 0.1 c.c. of old tuberculin (supplied by the New York City Department of Health) in a standard 1 c.c. "tuberculin syringe" graduated in tenths, twentieths, and hundredths of a cubic centimeter. Saline is drawn up to the 1 c.c. mark. An air bubble is then introduced, and by repeated inversion, the two solutions are mixed to form a 1:10 dilution of old tuberculin. The syringe is then emptied to the point where only 0.1 c.c. remains, and by repeated manipulations as above described, the dilutions 1:100, 1:1,000 . . . 1:100,000 are prepared, all in one syringe. Intradermal testing is then carried out, still with the very same syringe, after stopping at the dilution desired. That such a procedure introduces large errors in the estimation of the degree of skin sensitivity to tuberculin seems obvious and will become more evident.

*From the Laboratories of the Mount Sinai Hospital, New York.

†George Blumenthal, Jr., Fellow in Pathology.

Received for publication, July 24, 1940.

Patients on the Medical Wards of the Mount Sinai Hospital, New York City, were subjected to comparative tests: On the skin of one forearm (flexor surface) a 0.1 c.c. intradermal wheal was raised with a "1:100,000" solution of old tuberculin prepared as above described. The other forearm was similarly and simultaneously injected with 0.1 c.c. of 1:100,000 solution of old tuberculin prepared in individual test tubes as follows:

0.5 c.c. of O.T. + 4.5 c.c. of 0.9 per cent saline solution = 1:10 dilution.

0.5 c.c. of 1:10 dilution + 4.5 c.c. of saline = 1:100 dilution.

0.5 c.c. of 1:100 dilution + 4.5 c.c. of saline = 1:1,000 dilution, etc.

A single standardized 5 c.c. pipette was used to deliver the saline, but different 1 c.c. pipettes, calibrated in tenths of a cubic centimeter (also standardized*), were used for each dilution of old tuberculin, and were marked so that they would not be used for other dilutions. The amounts of solution were relatively large and easily handled, so that errors in measuring were thereby made minimal. Tuberculin of the same lot and preparation numbers was employed for all experiments (preparation No. 142, lot No. 173). Readings were taken at twenty-four, forty-eight, and often seventy-two hours. Those at the end of forty-eight hours are listed in Table I.

From Table I it is readily seen that even a 1:10,000 dilution prepared by the "multiple pipette" method is weaker than the so-called 1:100,000 dilution of the "single syringe" procedure. (Conforming to the practice of most workers in the field, we considered size as the main indicator of the intensity of the tuberculin reaction. This is the most easily quantitated feature of the response to any given dilution, and, we believe, roughly parallels the intensity of the reaction. Our scale for classification of results is indicated in Table I.)

TABLE I

DILUTION	NO. OF CASES	"SINGLE SYRINGE" PROCEDURE					"MULTIPLE PIPETTE" METHOD				
		DIAMETER									
		<5	5-10	11-15	16-20	>20					
		mm.	mm.	mm.	mm.	mm.					
		0	1+	2+	3+	4+	0	1+	2+	3+	4+
1:100,000	33	12	0	6	4	11	30	3	0	0	0
1:10,000	14* of above cases						1†	6	2	3	2

*These tests were done seventy-two hours after the former ones, always distal to areas previously tested. All cases in this group were previously positive only to the 1:100,000 dilution prepared by the "single syringe" procedure.

†This case was then retested with a 1:1,000 dilution prepared by the "multiple pipette" method and was found positive (2+). It was previously positive (4+) to a 1:100,000 dilution prepared by the "single syringe" procedure.

Another type of comparison was attempted on a series of 9 patients who had not been previously tested. In one forearm 0.1 c.c. of a 1:1,000,000 dilution ("single syringe" procedure) was intracutaneously administered, while simultaneously, 0.1 c.c. of a 1:10,000 dilution ("multiple pipette" method) was injected into the skin of the other forearm. The results (after forty-eight hours) follow in Table II.

*One cubic centimeter pipettes ordinarily do not deliver exactly 1 c.c. of fluid. Standardized pipettes are, therefore, recommended for more accurate dilution.

TABLE II

PATIENT NO.	"SINGLE SYRINGE" PROCEDURE	"MULTIPLE PIPETTE" METHOD
	1:1,000,000 DILUTION OF O.T.	1:10,000 DILUTION OF O.T.
1	2+	1+
2	2+	1+
3	0	0
4	3+	1+
5	2+	1+
6	1+	1+
7	1+	0
8	2+	1+
9	2+	1+

It is easily seen from Table II that the "single syringe" method is abnormally sensitive. That this is due to a combination of errors will be demonstrated.

The effects of adherence to glassware on the accuracy of tuberculin dilution were briefly studied. A comparison of dilutions prepared by the "multiple pipette" method was made with a similar set of dilutions prepared by using a single pipette throughout. Arbitrarily, the pipette was rinsed five times in each successive dilution in the course of the latter method. Four patients were tested simultaneously.

TABLE III

PATIENT NO.	1:100,000 DILUTION OF O.T.		1:10,000 DILUTION OF O.T. (TESTED 72 HOURS AFTER 1:100,000 TESTS)	
	MULTIPLE PIPETTE METHOD	SINGLE PIPETTE PROCEDURE	MULTIPLE PIPETTE METHOD	SINGLE PIPETTE PROCEDURE
1	0	0	0 (2+ with 1:1,000)	3+
2	0	1+	1+	Not tested
3	0	1+	3+ (16 by 15 mm.)	3+ (20 by 18 mm.)
4	0	1+	2+ (11 by 10 mm.)	2+ (14 by 13 mm.)

Undoubtedly the reasons for the discrepancy between the multiple and single pipette methods lie in the adherence to the pipette of sufficient amount of tuberculin to increase irregularly the concentration of a given solution above its presumed potency.

It will be noted that this discrepancy is less than that observed when the "single syringe" procedure is compared with the "multiple pipette" method. This is accounted for by another source of error in the syringe method, namely, the inadvertent seepage of fluid between the barrel and piston. We attempted to estimate the extent of this error.

Slightly more than 0.1 c.c. of old tuberculin was drawn into a standard tuberculin syringe. The syringe point was then turned upwards to expel the excess solution and the few small air bubbles which are almost always drawn in, so that only 0.1 c.c. of old tuberculin finally remained. When this was done, it became evident that, by capillarity and by gravity, tuberculin had seeped between barrel and piston along the shaft of the syringe to points varying usually between the 0.40 and 0.70 c.c. marks (results of a number of tests). This type

of seepage is clearly illustrated in Fig. 1. The volume of the space between barrel and piston was then actually calculated. This was done as follows:

The diameter of the piston was easily measured to the ten-thousandth of an inch by a suitable micrometer (Starrett Micrometer No. 113). Then the diameter corresponding to that of the barrel cavity was ascertained by the use of a gradually tapering metal cone which was inserted tightly into the syringe barrel as far as it would go. The diameter of the cone at the plane of impingement against the inner wall of the syringe was measured with the micrometer. This value checked with a measurement of a paraffin cast of the barrel cavity.

From these data it is possible to calculate the actual volume of fluid that seeps for a given distance between the barrel and the normally fitting piston, by means of the formula:

$$\text{Seepage Volume} = V - v = \pi h (R^2 - r^2)$$

where V and v represent the volumes of the barrel cavity and piston, respectively, over a given length, h , with R and r representing the radii of their

Fig. 1.—Note seepage of tuberculin into space between piston and barrel

respective cross sections. Calculated to the 1 c.c. mark, the seepage space is found to equal fully 13 c.mm. or an error of about one part in 75. This introduction of more concentrated old tuberculin into successive dilutions constitutes an additional source of error in this method of dilution.

If one adds to this the "human" error which must enter into the handling of so closely graduated an instrument, the use of a syringe method of dilution becomes still further open to condemnation.

It becomes apparent, then, that a method which employs a single syringe for both dilution and skin testing is open to many errors, most of which act in one direction, namely, to make the final dilution stronger than actually was intended. These are (1) the error due to the affinity of tuberculin for glassware; (2) the error due to seepage of old tuberculin between barrel and piston; and (3) the "human" error, which is greater with a finely graduated, relatively poorly controlled instrument, such as a syringe, as contrasted with a pipette.

COMMENT

Various workers have shown that individuals with active tuberculous processes are usually far more sensitive to tuberculin skin tests than are the posi-

tive reactors in control groups. Indeed, it has been suggested by some that the test with dilute tuberculin may be of use in screening out the actively tuberculous from the general population. Thus Ayman (1937) stated that 97 per cent of clinically nontuberculous patients failed to react to a 1:50,000 dilution of old tuberculin, while 93 per cent of patients with active (nonterminal) tuberculosis reacted positively if a 9 by 10 mm. skin lesion was taken as the measure of a true positive intradermal test. (This does not quite correspond to a 2+ by our scale of measurement.) Similar findings have been reported by others (Pan, 1937 and Hunt, 1939).

The few figures which we have presented lend confirmation to this impression inasmuch as none of our ward patients, all clinically nontuberculous, gave reactions to a 1:100,000 dilution ("multiple pipette" method) measuring 9 by 10 mm. Two individuals with active tuberculosis we tested, however, did react to high dilutions; one to 1:100,000, and the second to 1:50,000. On the other hand, fully 64 per cent of our nontuberculous patients reacted to a 1:100,000 dilution prepared by the "single syringe" procedure.

It is suggested that one of two methods be employed by the general hospital in the preparation of weak solutions of tuberculin: (1) that purified protein derivative be used. This is a substance of standard purity and potency which is relatively easy to handle with a minimum of error; or (2) that dilutions of old tuberculin be prepared in a central portion of the hospital, preferably in the bacteriologic laboratory where a proper technique may be employed. Dilute solutions* will, if sterile and preserved with 0.25 per cent phenol, remain potent for at least one week. (Long and Seibert; Lincoln, Raia, and Gilbert). The brief may be made for old tuberculin that it has a vast literature behind it.

For the actual test, different, labeled syringes should be used for each dilution, regardless of whether purified protein derivative or old tuberculin is employed.

SUMMARY

(1) The possible errors attendant in the dilution and use of old tuberculin for intradermal testing have been emphasized.

(2) The use of the "single syringe" procedure, which may give rise to an error of tenfold to hundredfold in the preparation of dilutions, is inadvisable for tuberculin as well as other biological solutions.

(3) A reasonably accurate method for preparing such weak solutions has been suggested.

(4) Confirmatory evidence as to the possible significance of skin sensitivity to high dilutions of tuberculo-protein is presented.

STAND FOR ASEPTIC OPERATIONS WITH HORSLEY-CLARKE'S STEREOTAXIC INSTRUMENT*

E. A. SPIEGEL, M.D., PHILADELPHIA, PA., AND
H. R. MILLER, M.D., NEW YORK, N. Y.

THE placing of cerebral lesions by means of the Horsley-Clarke¹ stereotaxic apparatus under sterile conditions can be facilitated considerably by employing the stand described below.

A base plate fixed to the animal board by clamps carries on each side an anterior column *A* (Fig. 1) for fixation of the orbits, and a posterior column *P* for fixation of the external auditory canals. *P* carries the aural pivot *p*, which is inserted in the funnel of the ear plug; *p* is fixed by a screw 1. *P* also carries a slot *g* into which the lateral bar of the horizontal frame of the stereotaxic apparatus is inserted. The screw 2 holds the frame in place.

The column *A* carries the following parts: (1) the infraorbital brackets *b* which rest upon the lower margin of the orbit; the brackets can be moved in the horizontal plane toward or away from the midline, and forward and backward, and are held in place by the screws 3 and 4. Thus the orbital and nasal plates of the Horsley-Clarke apparatus are not needed. (2) A horizontal bar *B* with posts *h* upon which the head holder rests. The bar *B* can be moved vertically in the slot *sl*, so that the upper jaws of the animal are pressed against the brackets *b*. (3) A groove *G* into which small horizontal bars fit that are fixed on the lateral bar of the horizontal frame of the stereotaxic apparatus. The screw 5, which can be rotated in the frontal plane, lies horizontally (as shown in the figure) when it is not used, and stands vertically when it holds the apparatus in place.

The axis of the aural pivots *p* and the undersurface of the infraorbital brackets *b* lie on a plane parallel to the base plate. The bottoms of the grooves *g* and *G* that receive the stereotaxic apparatus lie in a second horizontal plane so that the base frame of the stereotaxic apparatus is parallel to the plane determined by the external meatus and the lower margin of the orbits. The median sagittal plane is indicated by a small vertical plate *pl*.

*From the Department of Experimental Neurology, D. J. McCarthy Foundation, Temple University School of Medicine, Philadelphia, and the Montefiore Hospital, New York.
Received for publication, July 29, 1940.

The operation is performed in the following steps: The head of the animal (cat) is placed in a Czermak head holder (of the Harvard Instrument Company); the ear plugs and the aural pivots are inserted; the brackets *b* are placed on the lower margin of the orbits, and the upper jaws are pressed against

Fig. 1.—Stereotaxic apparatus held above the stand. *A*, anterior column with orbital brackets *b*, groove *G*, and bar *B* with posts *h* for head holder. *P*, Posterior column with aural pivot *p* and groove *G*. 1-5: screws; *pl* indicates the median sagittal plane. The needle of the stereotaxic apparatus is omitted.

the brackets by raising the bar upon which the head holder rests. The head is shaved and the brain is aseptically exposed. The stereotaxic apparatus is then placed on the frame and fixed by screws 2 and 5. Upon completion of the operation the stereotaxic apparatus is removed and the wound is closed.

TECHNIQUES FOR OBTAINING ELECTROENCEPHALOGRAMS USING OCULAR AND INTRANASAL ELECTRODES*

A. BARNETT,† M.D., NEW YORK, N. Y.

ELECTROENCEPHALOGRAPHIC procedures have now come into general use for the localization of certain types of brain pathology, such as tumors and epileptic foci.¹ For this purpose, it is desirable to take off potentials at points as close as possible to the pathologic locus. Up to the present time exploration has been limited to points on the outer surface of the cranial vault. The eye being, anatomically, part of the brain, it was thought to be of interest to develop a method for studying potentials taken directly from the surface of this organ. With an electrode applied to the cornea, the soft tissues within the orbit, including the eyeball, would behave, electrically, like a mass of absorbent cotton soaked in normal saline. Such a diffuse electrode would be expected to take off potentials (1) indirectly from the frontal lobe through the orbital roof; and (2) directly from the region of the chiasma and the hypothalamus via the optic nerve. An ocular electrode would thus be of value in studying electrical phenomena arising in these regions.

Libet and Gerard,² working with the frog brain, have recently shown that the olfactory bulb generates a rhythm of its own which persists after separation from the rest of the brain and which may be detected in olfactory bulb fragments weighing as little as 0.1 mg. These authors³ have also put forward evidence for the existence of a potential gradient along an electrical axis, extending between the occipital pole at one end and the olfactory bulb at the other. It seemed to be worth while, therefore, to provide a technique permitting the study of electrical events occurring in the olfactory bulb in man.

The purpose of the present paper is to describe procedures for obtaining cerebral potentials from the surface of the eye and from the interior of the nasal cavity in the vicinity of the olfactory nerve.

The Electrodes.—Fig. 1a shows an ocular electrode which may be applied directly to the eyeball without the use of an anesthetic. It is composed of a gold shell *b* provided with a platinum stem *s*. A fine wire *w* leads off potentials from stem *s* to the amplifier. Shell portion *b* is shaped to reproduce the form and dimensions of the so-called "contact" glass lenses now in commercial use for correcting errors in refraction. It is of circular section and measures 21 mm. in diameter at the base and 8 mm. in height. Attempts were made to utilize glass contact lenses as electrodes by metalizing the interior and exterior surfaces, but because of difficulties in obtaining a firmly adherent metal film and the

*From the Department of Psychiatry, New York State Psychiatric Institute and Hospital, New York.

Received for publication, July 30, 1940.

†Deceased.

danger of breakage, the solid gold type of electrode was adopted. In applying contact lenses to the eye, it is usual to half fill the lens with 0.5 normal saline prior to insertion. This makes the lens adhere firmly to the eyeball. Comparative tests with and without 0.5 normal saline showed that satisfactory electrical contact of the electrode with the surface of the eye could be obtained without recourse to saline. Tests carried out on my eyes with and without an anesthetic (holocaine) also showed that there was little gain in comfort by using the anesthetic.

The intranasal electrode represented in Fig. 1b is composed of a length of ordinary solder wire *a* enclosed in a sheath of "spaghetti" insulation *Sp* up to a point about $\frac{1}{4}$ inch from one end. A small wad of absorbent cotton *c* is twisted over the active end of the electrode and held in place by several turns of ordinary sewing cotton. A fine wire *w*, soldered to the opposite end of the electrode, leads off to the amplifier.

Fig. 1.—Electrodes for obtaining electroencephalograms: *a*, ocular electrode; *b*, intranasal electrode.

Experimental Procedure.—In preparing for electroencephalographic readings, with the subject in a sitting position, the usual lead pellet electrodes, their active sides covered with electrode paste, are first fixed in place by means of collodion in the occipital, frontal, and other regions to be explored with relation to the eye and nose. The subject is then placed in the decubitus dorsalis position, and the eye electrode is slipped into place between the eyelids. The subject is allowed to rest for a few minutes so as to become accustomed to the electrode and is instructed to seek a comfortable partially closed eyelid position which may be retained without blinking. This can be done by the average moderately relaxed type of subject without great difficulty. However, even in the best of subjects, occasional blink artifacts appear in the recordings, generally in groups, and are easily recognized by the appearance of large, rapid, potential changes.

Prior to placing the nasal electrode in position, the nasal cavity is swabbed first with 1:10,000 adrenalin solution, then with a 2 per cent solution of cocaine. The nasal electrode, moistened with normal saline, is then inserted as far as possible anteriorly, and is held in place by stuffing absorbent cotton into the free space between the electrode body and the nasal wall.

Records were made in a shielded, darkened room, using the two-channel, push-pull ink-writing recorder-amplifier described by Rahm.⁴ The time constant of the amplifiers was 0.5 second. Comparative tracings were made of eye occipital, nose occipital and fronto-occipital

potentials. These same potentials were also compared with those taken off from the occiput, forehead, eye and nose, using the lobe of the ear as a relatively inactive point of reference. The ear electrode was, however, not grounded. In order to insure against the possibility of coupling of the voltages led to the two amplifiers, leads feeding each channel were always taken from independent points. For example, if it was desired to compare the eye occipital with the ear occipital potentials, connections were made to the right occiput and the right eye for one channel, and with the left occiput and the ear for the other. Whenever possible, all leads were taken from the same hemisphere. The frontal and occipital electrodes were placed symmetrically at 3 cm. to the right and left of the midline. Only one ocular electrode

Fig. 2. Records I to X obtained with ocular and intranasal electrodes on a normal subject, and after hyperventilation on an epileptic patient. e, N, nose; R, ear; F, frontal; and O, occipital. All except those bearing the subscript L, which are from the left hemisphere.

was available for use and was mounted on the right eye. Simultaneous left and right fronto-occipital records of the normal subject for whom results are shown in Fig. 2 showed negligible differences in phase, frequency, and amplitude. Studies of both nasal and ocular potentials were carried out on a total of six normal subjects.

RESULTS

Fig. 2, records I to VIII, inclusive, show typical tracings obtained on a normal female, D. D., aged 26 years, with the ocular and nasal electrodes described above using various electrode combinations. Records I and II show

eye occipital (E-O) and nose occipital (N-O) potentials, each taken simultaneously with a fronto-occipital (F_L-O_L) tracing serving for comparison. All these curves are of about the same amplitude and frequency, exhibiting an alpha rhythm of 10 per second. In order to obtain a better idea of the contribution of the ocular and nasal components to the total recorded potentials, tracings were made using occipital ear (O_L-R) and frontal ear ($F-R$) leads, each taken simultaneously with eye occipital and nose occipital records. As will be seen from tracings III to VI, inclusive, both the occipital ear and frontal ear potentials are of lesser amplitude than those obtained with eye occipital and nose occipital leads. Finally, in tracings VII and VIII, eye-ear (E-R) and nose-ear (N-R) potentials are each shown with simultaneous fronto-occipital records for comparison. Both the eye-ear and nose-ear tracings contain a certain amount of alpha modulated by a faster rhythm of about 25 per second of lesser amplitude. The proportion of fast component was found to vary considerably in different subjects. As will be seen by a comparison of tracings III to VI with VII and VIII, the amplitudes of the eye-ear and nose-ear potentials are considerably less than the corresponding frontal ear and occipital ear potentials. The eye-ear potentials are of the order of 15 to 20 microvolts, while the nose-ear potentials are about 10 to 15 microvolts. A typical blink artifact is shown in the eye-ear record of tracing VII.

Since, as has already been pointed out, the occipital pole and the olfactory bulb of the frog represent, according to Gerard and Libet,³ opposite ends of an electrical axis along which a potential gradient exists, an attempt was made to follow in parallel the effect of an electrical change on the occipital and nasal potentials. For this purpose, simultaneous tracings were made of the fronto-occipital and nasal-auricular potentials on T. R., a male epileptic (petit mal), aged 21 years, before and after mild hyperventilation. The results are shown in records IX and X. Prior to hyperventilation (IX), occasional bursts of alpha were picked up by the nasal electrode coincidentally with the appearance of similar bursts in the fronto-occipital leads. After hyperventilation (X) the fronto-occipital potentials show practically continuous alpha activity of high, nearly constant amplitude. The amplitude and percentage time alpha in the nasal tracing were found to increase to correspond to the alpha change in the fronto-occipital leads.

DISCUSSION

In the eye records action potentials arising in the extrinsic muscles of the eye or in the muscles of the eyelids would be due to such action currents as may be necessary to maintain these muscles at a relatively fixed tonus, since rotation of the eyeball or movements of the lids appear on the records as large, rapid potential changes. The frequencies of the action potentials from these muscles do not appear to have been reported in the physiologic literature. It is significant to note that the 25 per second rhythm appearing in the eye-ear record (Fig. 2, VII) is also found in the corresponding frontal and nasal records (V, VI, and VII). This would argue in favor of its being of cerebral rather than of muscular, origin. Jasper and Andrews⁵ have reported the occurrence of a beta rhythm of 25 per second of precentral frontal origin.

Grinker and Serota,⁶ using an electrode inserted through the anterior wall of the sphenoid sinus, describe a 4 to 6 per second rhythm of hypothalamic origin. A study of the various eye tracings which, as has been pointed out, might contain hypothalamic potentials taken off by the optic nerve, failed to show the presence of slow waves of this kind.

It would be hazardous to attempt to explain the origin of the alpha nasal potentials. With the electrode in contact with the intranasal ramifications of the olfactory nerve, the alpha potentials picked off may arise in the olfactory bulb, in the frontal lobes,⁵ or even be transmitted from the occipital cortical centers.⁷ The hyperventilation experiment merely shows a parallelism in the response under a nasal electrode and from fronto-occipital leads, but it does not permit conclusions as to interrelations of a controlling nature between the two.

SUMMARY

Techniques are described permitting electroencephalograms to be made using a metal "contact" lens type of ocular electrode and a nasal electrode of simple design. Potentials taken off between one ear lobe and the surface of the eye or the interior of the nose show the presence of alpha rhythms together with rhythms of higher frequency having the character of beta waves. The eye-ear and nose-ear alpha potentials are of lesser amplitude than those obtained using occipital ear and frontal ear leads. In an epileptic person marked changes in fronto-occipital potentials caused by hyperventilation were accompanied by parallel changes in nasal-auricular potentials.

A METHOD FOR COUNTING THE LEUCOCYTES IN BLOOD CONTAINING GUM ACACIA*

J. VICTOR MONKE, M.S., BALTIMORE, MD.

AFTER the injection of gum acacia into the blood stream it is not possible to obtain satisfactory leucocyte counts using the customary Tuerek's solution (1 per cent acetic acid) as the lytic agent of the red blood cells. Instead of a clear microscopic field containing only faint shadows of the red blood cells, one obtains, in the presence of gum acacia, an incomplete lysis of red blood cell structure, and an amorphous debris representing clumps of red blood cells in varying states of disintegration. This difficulty was first observed by Huffman¹ and was briefly investigated by Walker.² The latter stated that N/10 hydrochloric acid could be successfully substituted for the acetic acid.

Similar difficulties in obtaining satisfactory lysis of red blood cells were encountered in this laboratory when attempts were made to determine whether or not the leucocytes were effectively removed from the blood stream of animals subjected to complete plasmapheresis with gum acacia-red blood cell-Locke's solution. Although Walker described satisfactory results using N/10 hydrochloric acid on human blood containing gum acacia, further investigation on our part showed it altogether unsatisfactory with dogs' blood and only partially so in human blood. In the face of this difficulty, an attempt was made to find another hemolytic agent which would make possible the counting of the leucocytes under the conditions described.

METHOD

A series of hemolytic agents was prepared. The result obtained with each was compared with the optimal result obtained by the use of dilute acetic acid on normal blood. For each comparison two portions of the same sample of blood were centrifuged. The plasma of one portion was carefully removed and replaced with an equal volume of 6 per cent gum acacia dissolved in 0.9 per cent saline. Both portions of blood were then shaken vigorously for fifteen minutes. A standard diluting pipette (1:20) was used to prepare the dilutions of the blood samples for the counting chamber (standard American hemocytometer with Levy-Hausser counting chamber†). The criteria required of a satisfactory lytic agent were first, that it produce a clear microscopic field free of any cellular debris, and second, that it permit a series of cell counts, the average of which and the probable error of which, was the same as that of a normal control sample in which the usual Tuerek's solution had been used as the diluting and hemolyzing agent.

OBSERVATIONS

1. *Acetic acid*: Dilutions of acetic acid, ranging from 0.5 per cent to 5.0 per cent, were made and tested for their effect upon the lysis of red blood cells. Solutions of 0.75 to 1.0 per cent acid are the most satisfactory. Concentrations higher than this reduce the red blood cells to pointlike specks. When gum acacia is present in the blood, the laking of the red blood cells does not take place. Instead, large clumps of cells form as the diluting fluid is drawn into the pipette. Under the microscope, the white blood cells are difficult to find because of the irregular, coarse, amorphous collections of red blood cells and cell debris which occupy the field. Numerous individual red blood cells appear as pale brownish yellow spheres or as unorganized masses.

2. *Lactic acid*: Dilutions of lactic acid were also made. Using normal blood, this acid is equally as effective as acetic acid. Its optimal concentration is about 1.8 per cent. In blood containing gum acacia, however, the lysis of the red blood cells results in the same amorphous precipitate as that encountered with acetic acid.

3. *Hydrochloric acid*: No concentration of hydrochloric acid was found which gives as clear a differentiation of leucocytes in normal blood as does the 1 per cent acetic acid. Although the N/10 hydrochloric acid permits the count of leucocytes in fields of normal blood, the fields are frequently filled with indistinct dotlike forms which cannot be brought into clear focus. The gum-containing blood always possesses a more pronounced background of these small pinpoint bodies. The leucocytes in some samples of human blood may be easily counted, while other samples have too much debris and too great a density of dots in the background to permit more than a hazardous guess on the number of white blood cells present. With dog blood it is impossible to make reliable counts on any samples of blood containing the gum acacia.

4. *Phosphoric acid*: As an example of another inorganic acid, phosphoric acid was tried and, under the same conditions of normality as the hydrochloric acid, it was found to be a somewhat better lytic agent for the normal red blood cells. However, it too is an unsatisfactory hemolytic agent in bloods that contain gum acacia.

5. *Saponin*: Since neither organic nor mineral acids promised to produce desirable results, a different type of lytic agent was investigated. It was found that the lysis of red blood cells, either in normal or in gum-containing bloods, was complete when the glycoside, saponin, was used. Saponin alone, however, did not produce a satisfactory microscopic field even though a range of solutions from 0.05 per cent to 5.0 per cent was investigated. The white blood cells appeared small and misshapen. Addition of any of the acids previously tested immediately produced the usual bad effect. Normal saline was finally added on the assumption that it would protect the white blood cells against undue distortion resulting from the osmotic effect of a hypotonic solution. A solution of 0.1 per cent saponin and 0.9 per cent saline was found to be quite satisfactory. The white blood cells were vitally stained by adding methyl violet in a concentration of 0.1 per cent to the saponin-saline solution. When two fields of normal blood, one diluted with acetic acid, and the other with a saponin-saline solution,

were compared side by side, the white blood cell counts of each were found to agree with a precision within the range of probable error of the measurement. When the leucocyte counts were made on blood containing gum acacia, they were found not only to be made easily, but also to be identical with those made on samples of the same blood containing no acacia. It was found that the rate of lysis by saponin is proportional to the concentration of the lytic agent, and to the number of cells. The solution of 0.1 per cent saponin in 0.9 per cent saline requires about five minutes for complete lysis of all red blood cells. This action may be watched under the microscope and the time of complete lysis may be readily determined.

In addition to the three types of lytic agents discussed, the simple osmotic lysis of "gum acacia" cells in hypotonic solutions of sodium chloride was also studied. The degree of hypotonicity at which red blood cells rupture was found to be unaffected by the presence of gum acacia, regardless of whether the gum had been added to the cells *in vitro* or *in vivo*.

DISCUSSION

No satisfactory explanation for this failure of the common lytic agents to cause the lysis of red blood cells, suspended in gum acacia, can be deduced from the data collected.

Simple lysis of red blood cells by hypotonic solution of inorganic salts is the result of osmotic equilibration.⁵ Variation in the rate of lysis by different inorganic salts is related only to the relative speeds of diffusion of the ions concerned across the plasma membrane. As mentioned in the previous paragraph, this action is not hindered by the presence of gum acacia.

Inorganic acids apparently cause lysis by some action other than an osmotic one. Bodansky³ lists phosphoric, sulfuric, hydrochloric, and nitric acids in the order of decreasing effectiveness as agents in the lysis of red blood cells. This investigator states that the pH is not the only factor concerned in the lytic action and that the effect is primarily not an osmotic one. More likely it is a reaction upon one of the units of structure in the cell membrane. This unit may very probably be the protein molecule, the orientated structure of which is destroyed by the acid. Gum acacia definitely interferes with this action.

The organic acids cause lysis of the red blood cell by a modified osmotic action.⁴ Increasing the osmotic pressure of the diluting fluid decreases the effectiveness of the lytic agent, but a close relationship is found between lipid solubility and the hemolytic activity of the organic acid. The higher the molecular weight and the more lipid soluble the acid, the more effective is the acid in equivalent concentrations. Gum acacia interferes markedly with this type of lysis.

Saponin represents a fourth type of lytic agent. "The fundamental action of a simple lysin such as saponin is imagined to be one in which the lysin reacts with some component of the red cell membrane, and which continues after lysis is complete until the cell component concerned is completely transformed as a result of a union with the lysin."⁵ Saponin causes an initial hemolysis followed by a complete stromatolysis. The simple lytic effect of a hypotonic solution is nonadditive to the more complex saponin lysis, implying an independence of the

two processes.⁶ Gum acacia does not affect this action. If acids are added to the saponin, the same precipitation is encountered which is observed when the acids are used alone. Saponin, acting on the lecithin portion of the stroma, may completely disorganize the cell and stroma. Inorganic acids acting on the cell membrane may act only on the protein structure in the membrane, causing their denaturation. The organic, fat-soluble acids, on the other hand, may not permeate so freely in the presence of gum acacia and thus not cause the expected hemolysis. The gum may act to change the surface tension of the stroma in the process of stromatolysis and thus effect the clumping of the cellular fragments.

Englebreth and Smith⁷ have also suggested the use of saponin as a lytic agent of red blood cells in the preparation of blood samples for leucocyte counts, but for a different reason. They call attention to the fact that white blood cells in citrated or heparinized blood may undergo a 20 per cent autolysis within several hours after drawing of the blood sample. This autolysis of the cells does not occur in the presence of 2 per cent sodium fluoride, indicating that the autolysis is caused by some enzyme, the activity of which is inhibited by the fluoride.

Fluoride of this strength, however, is not hypotonic enough to lysis the red blood cells. To overcome this difficulty, the authors employed a solution of 0.1 per cent saponin as a hemolytic agent. A solution of 0.1 per cent saponin, 1 per cent sodium fluoride, and 0.1 per cent methyl violet preserved the white blood cells so well that twenty-four hours after the mixing of the blood sample with the solution leucocyte counts could be made which were identical with those made immediately after the mixing.

SUMMARY

Leucocyte counts on bloods containing gum acacia are very difficult to make when the usual Tuercik's solution is used as the diluting and hemolytic agent. A solution of 0.1 per cent saponin, 0.9 per cent saline, and 0.1 per cent methyl violet is recommended instead. When this solution is used, complete hemolysis and stromatolysis of the red blood cells are obtained. The white blood cells are easily counted in both normal and acacia-containing bloods. The known factors concerning this lysis of red blood cells by various agents are discussed briefly.

AN AUTOMATIC PIPETTE AND A NEW INEXPENSIVE PIPETTING MACHINE*

JULIAN H. LEWIS, M.D., PH.D., CHICAGO, ILL.

THE bane of the serologist is the large amount of tedious pipetting involved in complement fixation tests, such as Wassermann reactions. Pipettes must be filled often, the meniscus carefully followed, and any attempt at speed often results in inaccuracies. Pipetting is a skilled procedure and unless one has had much experience, fatigue and cramps of the fingers slow up the process and tend to produce errors.

Attempts to reduce the inherent disadvantages of pipetting have resulted in the development of more or less automatic pipettes. For the most part these consist of syringes adjustable to deliver a given quantity of fluid. One type is operated manually and is filled by the recoil of a spring attached to the plunger. The amount of fluid delivered by the syringe is adjusted by a stopping device which limits the amount of material drawn into the apparatus. While this type of pipette increases the speed of pipetting over the usual glass pipette, there is still a loss of time in conveying it back and forth from the vessel containing the stock of reagent to the test tubes. The speed of pipetting depends on the development of coordination between this back and forth movement and the alternate compression and release of the plunger.

Another type of mechanical pipetting device is the so-called pipetting machine which is an adaptation of the original Woodyatt machine devised for the continuous intravenous injection of fluids at constant rates. It is likewise a syringe whose plunger is operated by an eccentric turned by an electric motor which also synchronizes a two-way valve. The amount of fluid delivered is adjusted by the length of stroke of the plunger, and the speed of operation is determined by the adjustable speed of the motor. The greatest objection to this device is its cost. Also, if more than one fluid is to be pipetted and unless more than one machine is available, it must be cleaned with each change of fluid and the mechanism readjusted if the volume to be delivered is also changed, both of which are time-consuming procedures.

Beeton, Dickinson & Co. manufacture an automatic syringe of the former type which is described in their literature as the "Improved Cornwall Syringe Number 1250." On request, this company interposed between the barrel of the syringe and the trocar, used as a pipette tip, a small two-way valve. This valve has a female "Luer-Lok" that connects with the syringe and a male "Luer-Lok" that takes the trocar. A side arm of the valve is fitted with a rub-

*From the Otho S. A. Sprague Memorial Institute and the Department of Pathology, University of Chicago.

Received for publication, August 10, 1940.

ber tubing that leads to the reservoir of the fluid to be pipetted. At the distal end of this tube is a perforated metal ball which keeps the tube submerged in the fluid. The apparatus is essentially a 2 c.c. Luer syringe mounted in a metal shell. The top of the plunger is attached by means of a yoke to a screw which

Fig. 1.—Diagram showing construction of automatic pipette.

Fig. 2—Separate parts of automatic pipette.

carries the plunger up and down. Its upward motion is given by a spring around the screw and is stopped by two lock nuts. The downward motion is obtained manually and is opposed to the force of the spring. The upward or filling stroke closes a valve leading to the trocar and opens a valve leading to the rubber tube and reservoir. The downward or emptying motion has the reverse

effect. Fig. 1 is a diagram showing the construction of the syringe. Fig. 2 is a photograph of the separate parts and, Fig. 3, of the whole assembled for use.

In adjusting the amount of fluid to be delivered the syringe is emptied 10 or 20 times into a small graduate. If this delivered amount is too small or too large, the plunger upstroke is adjusted by the lock nuts until it is correct. Once adjusted the amount delivered is remarkably constant.

By actual test it is found that from one-fifth to one-tenth of the pipetting time used in complement fixation tests with the ordinary pipette is used with this apparatus. No previous experience in pipetting is necessary for its use. A little practice with it enormously increases the speed. The operator simply aims the tip at the mouth of the tube, compresses the plunger, releases it, and it is ready for the next tube. Another advantage observed is that the fluid is forced into the test tubes rather than allowed to flow in as with an ordinary pipette. This completely mixes the fluids in the tubes and makes shaking unnecessary.

Fig. 3.—Automatic pipette assembled for use.

In the Kolmer complement fixation test for syphilis, five reagents, exclusive of the patients' sera, are used: saline, complement, antigen, hemolytic amboceptor, and red blood cells. The saline is used in two quantities, 1.2 c.c. and 0.5 c.c.; antigen is used in 0.5 c.c. amounts; complement in 1 c.c. amounts; hemolysin and red blood cells each in 0.5 c.c. amounts. For the greatest speed one may use one syringe for each of the reagents, two for the two quantities of saline, necessitating altogether six syringes. The price of the apparatus is reasonable enough to afford this. An alternative is to use three syringes, one for each of the reagents used in the same quantity. One, adjusted to deliver 0.5 c.c., may be used for saline, antigen, hemolysin, and red blood cells; an-

other, adjusted to deliver 1.0 c.c., for complement; and the third, adjusted to deliver 1.2 c.c., for saline. This necessitates cleaning the apparatus when solutions are changed.

Cheap Motor for the Automatic Syringe.—An apparatus for actuating the above syringe was devised using a compressed air type windshield wiper motor. The shaft of the motor, which is mounted on a baseboard, is fitted with a slotted arm to which is attached a connecting rod to a shaft housed in a bronze bearing. The end of the latter impinges against the plunger end of the above automatic syringe which is mounted on a block (Fig. 4). The stroke of the shaft is adjustable at the slot of the arm on the motor. The energy of the motor is used only for

Fig. 4.—Pipetting machine using windshield wiper as the motor.

emptying the syringe, its own spring bringing about the refill. The shaft that impinges against the syringe is broken at its end, and the parts are united with a coiled spring which takes up a slight overstroke and thus protects the syringe. A thick-walled rubber tubing of small caliber is attached to the two-way valve, and to this is fastened the trocar to serve as a delivery tip. A wide range of speeds is obtainable by adjusting the pressure of air to the motor.* This apparatus will, in every respect, give the same efficient pipette service as the much more expensive electrically operated pipetting machine. As the Woodyatt machine, designed for intravenous injections, was adapted for pipetting, so this apparatus, made for pipetting, can equally well be used for injecting.

*This apparatus was constructed in the machine shop of the Otho S. A. Sprague Memorial Institute.

AN IMPROVED TECHNIQUE FOR PNEUMOCOCCUS TYPING BY THE "QUELLUNG" REACTION*

A. B. PRANION, DETROIT, MICH.

THE "Quellung" reaction is the method of choice for typing pneumococci in sputum because of its time-saving element.

The following modification of the original method has been used by us for the last three years. We believe its advantages make it worth reporting.

Technique.—From the mucoid rather than from the purulent portion of the sputum four very thin smears are made in the form of a ribbon 10 to 15 mm. wide along the long axis of microscopic slides. The smears are allowed to dry at room temperature. Usually the first smear is dry when the fourth smear is completed. Two of the smears are marked with the group designations A, B, C, D, E, and F. One loopful of group A antipneumococcal serum is spread on the smear in a round area about 10 mm. in diameter. If methylene blue has been added to the antiserum previously, two loopfuls are used, otherwise another loopful of methylene blue is spread over the antiserum. A round cover glass, 18 mm. in diameter, is used to cover this area. No vaseline or jelly is needed. Similar smears are made with antisera of group B and C on the same slide; groups D, E, and F, are put likewise on a second slide and properly marked. These smears can be examined immediately under the 4 mm. objective.

COMMENT

The dry smear presents the following advantages: it affords better concentration of the antiserum, the microscopic field looks clearer, and additional smears can be made and saved for reference. (Our three-year-old smears still give excellent reaction.) In cases where sputum cannot be obtained, throat swabbings can be smeared on slides at the bedside, dried, and sent to the laboratory. Physicians in rural communities, where laboratory facilities are not available, can mail these dried smears to any laboratory. In our experience mailing of sputum has been very unsatisfactory. Dried smears can also be utilized in schools and colleges for teaching purposes. Hundreds of slides can be made from typed sputum and utilized for classwork whenever needed.

The advantages of the 4 mm. objective over the oil-immersion objective are twofold: (1) More area is covered in a shorter time, facilitating quick diagnosis. (2) The microscopic field can be studied with greater ease without disturbing the picture because the objective does not touch the smear. With oil-immersion objective the focusing throws the organisms off focus, or accompanying changes of pressure create currents which carry the organisms out of the field.

The Michigan State Board of Health Laboratories have adopted the above-described method. It is reported that the New York State Laboratories have also adopted it.

CHEMICAL

THE CONVERSION OF CREATININE INTO CREATINE IN NORMAL URINE*

S. M. HORVATH, M.S., AND D. B. DILL, PH.D., BOSTON, MASS.

IN CONNECTION with studies conducted in this laboratory that required twenty-four-hour collections of urine, some of the analyses were not made until two weeks after the samples had been collected. The finding of quantities of creatine greater than that recorded in the literature (Hobson, 1929) led us to suspect that conversion of creatinine to creatine had occurred, even though the samples of urine had been preserved with thymol and kept at room

Fig 1—Curves showing the average increase in the percentage of creatine (as creatinine) of total creatinine with time when urine is stored at room temperature and at 4° C. Series 1 represents urines collected in May, and series 2 represents urines collected in August.

temperatures. Such proved to be the case. On one patient three urines that had been analyzed fifteen days after collections were again analyzed after forty-one days at room temperatures. The average creatine percentage (expressed as creatinine) in total creatinine substances had increased from 7 to 18. The average values in the urines of two other men showed changes from 4 to 13 and from 12 to 25 per cent during twenty-six days following the first analysis.

*From the Fatigue Laboratory, Harvard University, Boston.

Received for publication, December 26, 1940.

We proceeded to study this problem in more detail. Since the storage temperature might be of importance, freshly voided urine was preserved with thymol and placed in the refrigerator at about 4°C . The volumes of the twenty-four-hour outputs were recorded, and two aliquots, also preserved with thymol, were taken. One was returned to the refrigerator, the other was left at room tem-

Fig. 2.—Curves illustrating various types and rates of conversion in aliquots of urine stored at room temperature and at 4°C .

peratures. Determinations of creatinine and of creatine plus creatinine (Folin, 1934), using the Evelyn photocolormeter, were made immediately and repeated at intervals thereafter. Creatine, expressed in terms of creatinine, was obtained by difference. Two series of experiments on a total of 4 persons were conducted, one starting in May and the other in August.

RESULTS

The data are presented graphically (Figs. 1 and 2). Total nitrogen determinations were made by the Kjeldahl method at the beginning and end of the experiments; no changes were noted. Aliquots kept at 4°C . maintained nearly

constant creatinine and creatine contents. In only 2 of 8 cases were creatine variations greater than 100 mg. found after standing in the cold for thirty days. After storage in the cold for 104 days, greater conversion occurred, amounting to from one-fifth to one-third of the total creatinine in three of the four samples of series I. In series II analyses on the thirty-seventh day showed less conversion of creatinine into creatine than was observed in series I after thirty days.

The aliquots kept at room temperature usually, but not always, showed a constant total creatinine. The urines of S. M. H. and B. C. (series I) gradually decreased in total creatinine with a concomitant rise in creatine. This was particularly apparent after a period of 104 days, when in B.C. the total creatinine was one-fifth its initial value (2.24 to 0.43 gm.), while the creatine value increased more than 2.5 times (0.12 to 0.33 Gm.) (Fig. 2). Analyses of other urines gave no greater variations in total creatinine than are within the accuracy of the method. Creatine values increase not only in per cent of total creatinine (Fig. 1) but also in actual amounts if kept at room temperature for more than nine days. This conversion occurs even when initial determinations gave zero values for creatine (Fig. 2).

Heintz (1847) showed that when he made preparations of creatinine from urine, creatine contaminated all his preparations. Liebig (1847), however, was only able to get creatinine from urine and showed that it was the use of ammonia and its compounds by Heintz that decomposed his creatinine zinc chloride to creatine. Dessaignes (1857) noted a slow conversion of creatinine to creatine, hastened by heat, to occur in aqueous solutions. The reversal of this reaction has also been recorded (Neubauer, 1866; Hahn and Barkan, 1920). Myers and Fine (1918) have recorded a gradual production of creatine in a pure aqueous solution of creatinine. Evidently heat, and perhaps ammonia, favor the conversion of creatinine to creatine; on long standing this may become appreciable.

SUMMARY

There is at first a slow and later a rapid conversion of creatinine if urine preserved with thymol stands at room temperature. At 4° C. conversion was observed on the thirty-seventh day and was pronounced by the one hundred and fourth day. While urine can be stored for a few days in the cold without appreciable change in either creatine or creatinine, it is a better practice to make these determinations within twenty-four hours after collecting the sample. In any case, preservation with thymol and storage in the cold are recommended.

URINARY PORPHYRIN BEFORE AND AFTER HYDROLYSIS*

EUGENIE H. MARCHLING, PH.D., NEW YORK, N. Y.

VERY little information is available about the form in which porphyrins are excreted in the urine. As a rule, no porphyrin can be extracted from urine by organic solvents prior to acidification with acetic acid. This basic step in urinary porphyrin analysis was first described in 1896 by Sallet,¹ who also noted the occurrence in urine of precursors of porphyrin—"chromogens"—which, although observed by many investigators,²⁻¹⁰ seem not to have been systematically taken into consideration when studying urinary porphyrin excretion in health and disease.

The extraction of zinc and copper complexes of porphyrins from urine acidified with acetic acid has been recorded.^{3, 11} The fact that no porphyrin can be extracted by ether from fresh urine of about pH 6 can be interpreted as evidence of conjugation. Assuming that the porphyrinogens are compounds of porphyrins with other inorganic or organic substances and differ in their stability to acetic acid, one may reasonably expect that hydrochloric acid would be more effective in bringing about a complete cleavage. Preliminary experiments have indicated that a widely varying rise occurs in the porphyrin level of urines on treatment with strong hydrochloric acid (see Tables I and II). The ratios of the porphyrin values so obtained varied widely for different persons, but were constant and in general reproducible for the same individual.

*Attack of indigestion.

EXPERIMENTAL

After the hydrolysis of the hypothetical chromogens with hydrochloric acid, it was necessary to neutralize the solution with alkali and then to acidify it with glacial acetic acid prior to the extraction of coproporphyrin with ether. The treatment with hydrochloric acid considerably reduces the formation of disturbing emulsions during the ether extraction. However, it brings about a formation of urinary pigments other than porphyrin,^{12 13} and these must be separated before the spectroscopic identification and estimation of porphyrin can be carried out. Indirubin and indigo blue, which are simultaneously extracted with coproporphyrin by ether from the suitably prepared acetic acid solution, can be removed by means of 5 per cent hydrochloric acid, which extracts only the coproporphyrin.

Two types of experiment were performed systematically: Two 300 c.c. portions of each urine specimen are used for the determination of the urinary porphyrins. One is acidified with 30 c.c. of glacial acetic acid and the other with 30 c.c. of concentrated hydrochloric acid, and both are allowed to stand for at least two hours. The hydrochloric acid treated specimen is then made alkaline with potassium hydroxide and acidified with glacial acetic acid. Tap water is used to cool the solution during these operations. Both specimens are now treated in the same way, according to the accepted methods (Fischer¹⁴ and Rimington¹⁵). Each solution is shaken with three successive portions of ether; the combined ethereal solutions are washed first with water and then repeatedly with 5 to 10 c.c. quantities of 5 per cent hydrochloric acid to recover the porphyrin (coproporphyrin). This hydrochloric acid solution is neutralized and acidified with glacial acetic acid, and coproporphyrin is again taken up in ether. This ether extract is made up to a known volume in a 25 c.c. graduated cylinder; the porphyrin rarely requires further purification.

The spectroscopic examination was made with a Bausch & Lomb wave length spectrometer, essentially as described by Kapp and Coburn,¹⁶ hematoporphyrin, which spectroscopically resembles coproporphyrin very closely, being employed as a standard.¹⁷ When the spectra (from two light sources) of hematoporphyrin and coproporphyrin in ether, as well as in hydrochloric acid solution of about the same concentration, were superimposed, using the comparison prism of the Bausch & Lomb Laboratory wave length spectrometer, no difference could be seen.¹⁸

A series of standard hematoporphyrin solutions in ether were prepared, and the limits of their absorption bands were recorded. Two spectroscopic charac-

teristics of coproporphyrin were found to be particularly useful for the quantitative estimation of urinary coproporphyrin: a relatively faint band at about 5980 Å indicating the presence in 16 c.c. (200 mm. cell) of at least 14 micrograms, and the coproporphyrin band in the red at 6230 Å indicating the presence of at least 3 micrograms. The point at which an absorption band is just visible can be reached by suitable dilutions, or by using cells of different lengths.

Uroporphyrin was isolated from the acetic acid aqueous phase remaining after ether extraction of coproporphyrin. This residual solution was slowly passed through an adsorption column of Merek's aluminum oxide and eluted with 12 per cent ammonia.¹⁹ Uroporphyrin is not found in normal urine and no uroporphyrin standards are, as a rule, available. In the case of a patient with light sensitivity the ammoniacal uroporphyrin solutions obtained by elution from hydrolyzed and unhydrolyzed identical aliquot portions of urine when compared colorimetrically showed a threefold increase of uroporphyrin in the hydrolyzed portion.

SUMMARY

Increased yields of urinary porphyrin can be obtained by hydrolysis with hydrochloric acid.

By comparison of the porphyrin yields from unhydrolyzed and hydrolyzed samples of the same urine, it is possible to determine the ratio of total porphyrin to porphyrin present in form of porphyrinogen or chromogen.

PREPARATION OF CHOLESTEROL EMULSION FOR EXPERIMENTAL INTRAVENOUS ADMINISTRATION*

WARREN H. COLE, M.D., AND HERMAN CLARK, B.S., CHICAGO, ILL.,
AND NATHAN A. WOMACK, M.D., ST. LOUIS, MO.

THE oral and intravenous methods of administration of cholesterol known to us will not produce a significant elevation of the blood cholesterol. After experimentation with variations in technique of preparation of emulsions, we were able to prepare emulsions in concentration as great as 2, 3, or 4 per cent by dispersion of the emulsion in steam. No claims for priority are made, since the method is perhaps used extensively commercially. Homogenization, a principle commonly used in the dairy industry, is a very efficient method of producing emulsions, but the homogenizing machines usually available are so large that several gallons are necessary for their function, thereby making the process for our purpose prohibitive financially. Moreover, preheating of the ether-oleate-cholesterol solution, as utilized in our method, seems important in the emulsification, and might be difficult to attain in a homogenizer.

METHOD

1. Dissolve 3 Gm. of cholesterol in about 50 c.c. of ethyl ether.
2. Dissolve 1 Gm. of sodium oleate in sufficient water to make 100 c.c. In our experience tap water is *much superior* to distilled water, as far as the emulsification process is concerned.
3. To solution No. 2, contained in a 500 c.c. Erlenmeyer flask, slowly add solution No. 1, stirring or swirling constantly. This ether-oleate-cholesterol solution is now ready for dispersion, which is brought about by allowing a small stream of the ether-oleate-cholesterol solution to come in contact with a jet of steam at the end of a T-tube, as illustrated in Fig. 1.

The apparatus herein described can be set up with equipment found in practically any laboratory. A pressure cooker or small autoclave (Fig. 1) is heated until a pressure of 15 or 20 pounds is obtained. The valve is opened and the steam is allowed to pass through the T-tube surrounding the tube which conducts the cholesterol solution. After the glassware is hot, the ether-oleate cholesterol solution is allowed to run out; it is heated by the steam surrounding the glass tube conducting it, and flows out of the 1 mm. opening as a fine spray, coming in immediate contact with the steam emerging from the tip of the outside tube. It is important that the size of the steam spray be adjusted by moving the inside tube very slightly in or out, until a mixture is obtained producing a fine emulsion. The emulsion can be tested for size of the globules

*From the Departments of Surgery, University of Illinois, College of Medicine, Chicago, and Washington University School of Medicine, St. Louis.
Aided by a grant from the Committee on Scientific Research of the American Medical Association.

Received for publication, January 20, 1941.

in a few moments by observation under the microscope. When first using the apparatus, it will be necessary to experiment considerably with the size of the steam jet before a satisfactory emulsion with globules less than 4 or 5 microns in diameter will be obtained. Passage of the emulsion through the apparatus a second time will improve the emulsion. Preliminary to the second dispersion the inside tube is pushed forward, narrowing the steam outlet. It is not wise to pass the solution through more than twice, since the volume will be increased by condensation of steam, thereby cutting down on the concentration. After a little experience with the apparatus, it will be found that the concentration of cholesterol in solution No. 1 can be increased beyond 6 per cent.

FIG. 1.—Apparatus used in emulsifying cholesterol. By means of a pressure cooker or autoclave, steam is forced through a T-tube coming in contact with the ether-oleate-cholesterol solution as it emerges through the tip of the small tube within the T-tube. Insert represents a longitudinal section of the T-tube and illustrates how steam entering at the arm of the T-tube heats the ether-oleate-cholesterol solution and emulsifies it at its exit. The outside diameter of the inside tube conducting the ether-oleate-cholesterol solution is 5 mm. The end of the inner tube has previously been drawn to a point in a flame; the diameter of the opening at the end of this tube, where the solution emerges, is about 1 mm. This bevel at the end of the inner tube allows it to be pushed toward the end of the T-tube until a very small rim of space remains through which the steam emerges to come in immediate contact with the ether-oleate-cholesterol solution. The diameter of the T-tube is 1 cm., but the end has previously been reduced in the flame to a diameter of about 1 mm. The T-tube being short has been spliced to permit adequate heating of the solution. The larger flasks marked A must be used during the first dispersion, because the evaporation of the ether causes a lot of foaming. On account of rapid evaporation of ether from the ether-oleate-cholesterol solution, care must be exercised in the prevention of fire.

A variable amount of crystallization will take place, but not sufficient to affect the concentration of cholesterol in the emulsion more than 0.2 or 0.3 per cent. After the emulsion has cooled, it is preferable to subject it to centrifugation. This removes the crystals and apparently also a considerable proportion of the large globules. Such an emulsion will keep for many days or weeks.

Occasionally an emulsion breaks up and crystallizes to a hopeless degree. We have not been able to explain satisfactorily these failures. The emulsion has not as yet been tried on human beings, but sufficient quantity can be given to animals (rabbits) to elevate the blood cholesterol by 50 per cent after intravenous administration.

ELIMINATION OF STANDARDS AND NOMOGRAMS IN THE DETERMINATION OF WHOLE BLOOD SPECIFIC GRAVITY BY A FALLING-DROP TECHNIQUE*

BENJAMIN M. KAGAN, M.D., RICHMOND, VA.

IN 1924 Barbour and Hamilton¹ described an apparatus for the determination of blood specific gravity by a falling-drop technique. In 1926² they found that in order to obtain sufficient accuracy with the xylene-bromobenzene mixture they used, it was constantly necessary to use aqueous standards and a nomogram. In 1930 Moore and Van Slyke³ tried this method to obtain plasma specific gravity and found it unsatisfactory for routine use because the maintaining of aqueous standards accurate in specific gravity to 1×10^{-4} is so difficult and because constant reference to a nomogram is necessary.

In 1938⁴ I reported a falling-drop method which eliminated the necessity for standards and a nomogram. At that time it was adapted specifically for use with serum and plasma.⁵ Since 1938, however, numerous requests have come for a method of determining the specific gravity of whole blood which would likewise eliminate the use of standards and the nomogram. This determination is desired in order to follow the changes in blood specific gravity during such conditions as shock, dehydration, anemia, and fluid administration, and to study blood volume changes. I have, therefore, adapted the latter method for use with whole blood as described below.

METHOD

It was found that a mixture of methyl salicylate and mineral oil, such as used for the determination of serum or plasma specific gravity, did not permit as large a range as was desirable for use with whole blood.

With the cooperation of the E. H. Sargent & Co. of Chicago, a medium was prepared which consists of a mixture of specially purified petroleum oil and methyl salicylate. It has a specific gravity of 1.0367 25°/25° C., a viscosity of 26.4 cp 25° C., and permits a range of 1.0380 to 1.0720 25°/25° C. This mixture, like the mineral oil-wintergreen mixture for serum and plasma, has a boiling point of over 220° C. and is stable. There is no danger of change in the oil from evaporation such as occurs in the xylene-bromobenzene mixture used in the method devised by Barbour and Hamilton. (A mixture of mineral oil and methyl salicylate prepared four years ago has been tested repeatedly and

has shown no significant change.) It is this stability which eliminates the necessity for standards by permitting standardization of the oil itself.

The apparatus and technique for determining whole blood specific gravity are identical with those described for serum or plasma protein determination in a previous article.⁴ Briefly, the time taken for a drop of blood to fall a given distance is determined, and the temperature at which this is done is observed; then, by means of a formula or a table, the specific gravity is obtained from the

time and temperature readings. Owing to the high viscosity of the medium used, the distance through which the drop must fall need be only 10 cm. as compared to 30 cm. through the xylene-bromobenzene mixture. This shorter tube allows more uniform temperature throughout the oil and makes transportation of the instrument easy. It can, therefore, be used conveniently in the operating room or at the bedside.

The specific gravity of whole blood is derived from the following formula:

$$\text{Specific Gravity} = K/t + d$$

where K and d are constants for the temperature at which the determination was done and t is the falling time. These constants are shown in Table I. With this formula the mean deviation is less than $\pm 1 \times 10^{-4}$ and the maximum deviation is $\pm 2 \times 10^{-4}$ when compared to specific gravity obtained by pycnometry. For those who require accuracy only to $\pm 1 \times 10^{-3}$ or for rapid estimation in the operating room, Table II is convenient.

SUMMARY

A new oil is reported for use in the determination of whole blood specific gravity by the falling-drop technique previously described by the author.⁴ This oil has the following advantages over the xylene-bromobenzene mixture described by Barbour and Hamilton:

1. Elimination of the use of standard solutions, thus reducing danger of errors which result from changes in these solutions and also making for greater simplicity of technique.
2. Higher boiling point eliminates changes in the oil through evaporation.
3. Higher viscosity permits use of a tube about one-third as long, thus reducing chance of error due to difference in temperature at different levels in the instrument. This also facilitates its use in the operating room or at the bedside because it is more easily transported.
4. It permits substitution of a simple formula for the nomogram.

Using this formula, accuracy may be obtained within $\pm 1 \times 10^{-4}$ in specific gravity. A table is also given which permits direct reading of the specific gravity from the falling time and temperature for those who desire accuracy of only $\pm 1 \times 10^{-3}$.

THE ANAEROBIC DRAWING AND SAMPLING OF BLOOD FOR GAS ANALYSIS*

J. VICTOR MONKE, M.S., BALTIMORE, MD.

THE methods generally used in the anaerobic drawing and sampling of blood for blood gas analysis are described by Peters and Van Slyke.¹ The method in most common use is one requiring that blood be drawn from an artery or vein into a vessel containing a layer of mineral oil. Since the oil retards the diffusion of carbon dioxide out of the blood, and the oxygen of the air into it, the oil layer floating on the blood acts as a moderately satisfactory airtight cap. In order to obtain a sample of blood for analysis in a Van Slyke and Neill manometric apparatus, it is necessary that the tip of a stopcock pipette be passed through the oil into the blood. Invariably, a small amount of oil is introduced into the pipette which later causes more or less difficulty in the delivery of the sample into the chamber of the manometric apparatus. A more cautious method, advised by Austin and co-workers,² involves the introduction of drawn blood into a mercury-filled system, the mercury being slowly withdrawn from a receiving vessel into a leveling reservoir as the blood is admitted into the receiving vessel. This most accurate of methods, however, is best carried out by two individuals. If a number of samples are to be drawn within a short time, its use necessitates the possession of a large quantity of mercury, and many pieces of apparatus.

These difficulties are obviated in a procedure which has been used in this laboratory for several hundred analyses of blood oxygen. A 10 c.c. syringe, selected for its smoothly moving, closely fitting plunger, is filled with and then emptied of an anticoagulant, e.g., saturated potassium oxalate. Enough oxalate remains in the syringe to fill the air space in the nipple of the syringe and to form a film on the sides of the barrel. A needle is attached to the syringe, and the sample of blood is drawn. If the sample is of the order of 5 c.c. or more, the volume of anticoagulant remaining in the syringe is an insignificant amount of the sample drawn. After the collection of the sample, the barrel and the plunger of the syringe are held firmly in the right hand while the needle is removed from the nipple of the syringe. A small amount of mercury is then drawn into the syringe from a shallow dish. The syringe is pointed upward, and a drop of blood is forced out through the nipple. A small needle, the lumen of which is no longer patent, is attached tightly onto the nipple of the syringe, providing an airtight cap for the syringe. The mercury may now be shaken back and forth fifteen or twenty times to insure that all the blood is mixed with the anticoagulant.

*From the Department of Physiology, School of Medicine, University of Tennessee, Memphis, and the Department of Physiology, School of Medicine, University of Maryland, Baltimore.
Received for publication, August 10, 1940.

In this manner any number of anaerobic samples of blood may be drawn in rapid succession without need of any equipment other than sufficient syringes. If a period of time greater than a few minutes is to elapse before the analyses are made, 20 c.c. syringes may be used instead. In this case, the longer distance separating the tip of the plunger from the upper end of the barrel gives added protection against the possibility that blood gases may diffuse along the inner wall of the barrel. If the sample is to be kept for any length of time, it is advisable to chill the syringe in an ice bath or icebox.

Filling the stopcock pipettes from a syringe is a simple procedure possessing several advantages over older methods. If the syringe is placed flat on a table in such a position that the nipple extends over the edge of the table, the syringe may be held firmly, without danger of admitting air, while the cap is removed from the nipple. A stopcock pipette, to the upper end of which has been attached a 2 cm. length of gum rubber tubing, is attached to the nipple of the syringe. With the stopcock open, the whole assemblage is turned vertically, and the blood is transferred from the syringe to the pipette by gently pressing the head of the plunger against the table top. When the blood level has almost reached the delivery tip of the pipette, the stopcock is closed. The assemblage is again placed horizontally, the stopcock pipette is removed, and the small occluded needle is replaced on the syringe. The layer of blood exposed to the air while passing through the bulb of the pipette is discarded from the tip as the blood level is brought from the top of the pipette down to the upper calibration mark. In this manner the blood actually admitted into the chamber of the gasometric apparatus does not come close to an air interface, and is not subjected to any change in pressure.

The validity of this procedure was checked against the older mercury displacement method by analysis in duplicate of a series of twelve samples of blood in the gasometric apparatus. The average variation in the values for oxygen content was of the same order in each series. The syringe method was found to be simpler and more rapid. It made possible easy chilling and storage of the sample, and permitted the filling of the stopcock pipettes under optimal conditions.

MEDICAL ILLUSTRATION

THE CRAYON SAUCE TECHNIQUE FOR MEDICAL ILLUSTRATION*

CARL DAME CLARKE, PH.D., BALTIMORE, MD.

FOR the past fifty years a particular procedure has been employed pre-eminently for the illustration of medical subjects. This is known as the crayon sauce or pencil dust technique. From time to time examples of this type of work have come to light which could possibly date the discovery of the procedure before the period previously mentioned. It can certainly be said that Mr. Max Broedel, of the Johns Hopkins School of Medicine, rediscovered the technique and used it extensively in scientific illustration. Prior to this time the pen-and-ink, wash, charcoal, and pencil line techniques had been employed. The latter method was applied particularly for lithographic reproduction, the lithographic grease crayon being used directly on the stone. The pen-and-ink technique was employed to a great extent for the illustration of science during the same period and still is the most popular method of pictorial representation. Wash drawings have been made for many years, but these are rapidly falling into disuse for the illustration of medicine. This is still the most popular method for obtaining drawn tone illustrations in the commercial art field. In the sciences, the necessity of representing on paper a myriad of details called for an exacting and flexible technique, such as that afforded by crayon sauce. The crayon sauce drawing can be developed rapidly in comparison with other techniques.

Knowledge of the Subject to Be Illustrated.—To make the best scientific illustrations one must be able to draw and have a thorough knowledge of the subject to be illustrated. An untrained draftsman who knows biology often can make a better representation of a biologic subject than the trained artist who has little conception of what he is picturing. For example, let us consider the scientific art of medical illustration in the sense of drawing alone. Anatomy is the foundation upon which medical art is built. Without a knowledge of this subject, without this foundation, further work is likely to be done in confusion and fall short of producing a comprehensive illustration.

The average layman has no more knowledge of visceral anatomy than he has of the inside of a house whose doorways he has never entered. Therefore, to draw anatomy one must know anatomy. The artist must be able to draw not only what he sees, but also what he does not see yet knows to exist. For instance, in illustrating a surgical procedure the artist often is handicapped by having to view his subject through a small and poorly lighted incision. The structure

*From the Department of Art, School of Medicine, University of Maryland.

that he wishes to see is generally covered with blood, superficial fat, mucus, and other obstructions that prevent a clear view. However, if his knowledge of human anatomy is clear and concise, he is able to reconstruct the parts that he does not see but knows to be present. Such knowledge can be obtained only from careful dissection of the cadaver.

The preparation of illustrations for scientific publications is an art in which accuracy and technical detail are absolutely essential. These drawings should have modeling to such an extent that the third dimension is shown with stereoscopic clearness. This profession belongs in a class of its own. The picture produced by the artist in this field must tell a story without a climax. It is a statement of facts as they are, with only a written history of the case to describe the development of the subject portrayed. It is a realistic art in its entirety, an art in which impressionism, cubism, futurism, or any other branch of modernism or ultramodernism has no place whatever.

Types of Medical Drawings.—In explaining or teaching a new operative procedure it is essential that the surgeon have the most important steps of the operation illustrated, because with mere words it is difficult to convey even to the minds of well-trained fellow surgeons the technical details of an operation they have never witnessed.

Practically every operative procedure should be illustrated with black-and-white drawings since color is unnecessary in showing the mechanics of surgery. Once a specimen is removed from the body, however, it often is necessary to make drawings in color. Frequently a diagnosis may depend on the color of a specimen. An accurately colored drawing of such a specimen helps in teaching methods of diagnosis. As a rule, the unusual specimen is the one placed in the hands of the artist.

Drawings play an important part in the teaching of anatomy. The degree of perfection and the importance of a book on anatomy depend largely on the excellence of the illustrations. This is true not only of medical books but of scientific books as a whole.

Training the Medical Artist.—The training of the artist develops his natural ability to observe minute details and to make a mental picture of them. Later he is able to reproduce them on paper because in his mind the picture is clear and complete. In the average person this mental picture is hazy and unfinished; it is completely lacking in the necessary details required by the artist.

In medical illustration it is often customary to make drawings to scale. The artist uses rulers or calipers to determine the correct proportions on paper. As he gains experience he is able to visualize such proportions and combine them on paper in true ratio and proportion to the model. This grasping and reproducing of details, plus the ability to measure with the eye, determine an artist's ability. He must not only make illustrations the exact size as his model, but reductions and enlargements in ratio and proportion to the model or subject he is drawing. For example, he may reduce an entire body to accurate proportions on a sheet of paper that is only 15 inches high. In contrast to this he may enlarge a tiny embryo to accurate dimensions on a piece of paper of the same size.

The following is a description of the materials needed for making medical drawings and their use:

Sketch Paper and Pencils.—In naming the materials used in making medical drawings, let us first differentiate between the paper or board upon which the final drawing is made and the paper for the preliminary sketches. The word *final* is used because such drawings require much detail work and often many corrections and refinements before the drawing is completed. Sketches and outlines are made on an ordinary grade of thin *drawing paper* or a good grade of *typewriting paper* before the final drawing is attempted. After the sketches are prepared and passed on by the biologist or physician who is ordering the

Fig. 1.—Numbers 1, 2, 3, 4, and 5 are pencils, 1 being the Conté or soft pencil from which the pencil dust is obtained; 2, 3, 4, and 5 are Wolff pencils varying in hardness, H being the hardest, and BB the softest. BB and B are used most in developing the crayon sauce drawing. No. 6 is a charcoal holder, in the left-hand side of which is a pointed eraser for removing fine details. The right-hand side is a pointed cork for softening pencil lines. No. 7 is another charcoal holder, in the left-hand side of which is inserted a pad of chamois for softening and blending large areas. The right-hand side contains a blunt cork for softening and blending small areas. No. 8 is the engraving tool or scratcher used for etching out high lights and producing fine, sharp white details. The right-hand side of No. 8a shows how the end of this tool is ground flat. This is the same surface as is presented in No. 8.

drawing, the real work begins. All corrections and refinements should be made in detail on a sheet of thin drawing paper or *sketch paper*, as it is called by medical illustrators. For this purpose a *Conté No. 3 carbon pencil* (Fig. 1, 1) is used; however, a *Wolff BB* (Fig. 1, 5) or a *Wolff B* (Fig. 1, 4) will be found satisfactory. The Conté pencil is soft and transfers easily. The transferring process is essential for making a really fine drawing. The Wolff BB and B pencils are also soft, but neither is as soft as the Conté No. 3. Fig. 1 shows four Wolff pencils of various degrees of hardness or softness. BB is the softest of the four, B is a little harder than BB, HB is harder than B, and H is a comparatively hard pencil. In the preliminary sketches either the BB or the Conté pencils will

be found best and will transfer more readily. All the pencils shown in Fig. 1 are used in making the final drawing on Ross stipple board.

Transfer Process Using an Extra Sheet of Paper.—After the sketch or preparatory drawing is worked up in line, this paper is placed face down on a second sheet of thin paper. By rubbing the back of the first sheet with the fingernails while holding the two sheets firmly together on the drawing board or some other flat surface, a transfer of the soft pencil lines to the second sheet is accomplished. This second sheet will show the drawing in reverse. The parts of the original drawing that were on the right-hand side will now be on the left-hand side on the transfer. In accomplishing this it should be borne in mind that the two sheets must not slip even a fraction of an inch from each other or the transfer will be blurred or out of register. There are various methods of carrying out this procedure. Some artists thumbtack both sheets to a drawing board. If this is done, instead of using the fingernails, which may become sore from rubbing the back of the original drawing, the round or top end of the engraving tool, as seen in Fig. 1, 8, is used. Another method is to clamp together the two sheets of paper with paper clips or clamps. When the drawing to be transferred is no larger than an ordinary sheet of typewriting paper, a hospital chart holder serves excellently to hold the sheets together for the transfer process. The transfer is effected more easily with a few sheets of paper, or a smooth-surfaced piece of cardboard placed under the sheet to which the transfer is to be made. This transfer, which as previously explained is in the reverse order, is called a *negative* (Fig. 2).

Ross Stipple Board.—Before discussing the negative further, let us consider the board or material upon which the final drawing is to be made. This board is known as *Ross stipple board, No. 00-dull* and can be purchased from most of the larger art supply dealers. The surface of this board is prepared in the manufacturing by placing a layer of chalk and sizing on a thin cardboard. This surface is then pressed with a metal plate to obtain the stippled effect of a series of small raised dots which act as teeth to hold the carbon of the drawing pencils. It was necessary for the early medical illustrators to prepare their own stipple board, which they did by applying the chalk and sizing to a flat, finely sandpapered board. However, the material now can be purchased without difficulty.

Mounting the Stipple Board.—Before preparing to work up the final drawing on this stipple board, the board should be mounted on heavy cardboard, preferably with rubber cement or by the dry mounting process. A water paste or glue can be used, but it is likely to buckle or curl both the stipple board and the mount. This can be corrected by pasting on the back strips of paper running in the opposite direction from the buckle or bend. As these strips of paper dry they contract and pull the cardboard back to a flat surface.

The negative transfer previously mentioned is placed face down on the mounted stipple board and held in position by thumbtacks, paper clamps, or the hospital chart holder, then rubbed with the fingernails to accomplish a second transfer to the stipple board. Do not rub this second transfer with the round

end of the engraving tool since it may injure the chalk surface of the stipple board that is underneath. This second transfer is in the same order as the original drawing and is called a *positive*. The positive is naturally weak from two transfer processes but serves as a good outline from which to make the finished drawing.

A.

B.

C.

D.

Fig. 2.—Method of making sketch and transfers for the final drawing. This illustration is of a fetal heart. The original drawing was enlarged rather than reduced from the model.

Transfer Process Using One Sheet of Paper.—A second method of making a transfer is as follows:

First, turn the original sketch over face down on a piece of glass under which is an electric light, or hold it up to a window pane. Then with a soft pencil trace the lines that show through the paper. This tracing will be in nega-

tive order. Clamp the sketch, face up, over the mounted stipple board on the chart holder and trace over the original lines of the sketch. The second tracing will cause the lines on the under side of the sketch paper to leave their impression on the stipple board. The transfer processes are necessary because the stipple board does not readily lend itself to making corrections. However, it does make it possible to present detail, texture, and feeling that no other material presents.

The Eraser.—Some illustrators work in the well-known wash method, but this procedure takes longer and requires more skill in handling, and corrections are equally hard to make. Lighter areas in the pencil dust drawing are accomplished by erasing with a *nigrivorine* (No. 3) eraser, half of which has been mounted on a charcoal holder, as seen in the left end of Fig. 1, 6. This eraser must be kept pointed at all times so that detail work may easily be accomplished. There is a similar product called Weldon Roberts shading rubber No. 200.* This serves as well for shading and erasing medical drawings done on Ross stipple board.

Frequently these erasers are a little too soft for a great amount of detail work, even if they are kept pointed. To overcome this difficulty they may be placed in a small cloth bag and thumbtacked outside the window, thereby exposing them to the weather. In three or four months they have hardened sufficiently to work up the detail freely. The *nigrivorine* erasers are not expensive. They are made in France and may be bought at most art supply stores. However, the artist should not depend on this particular eraser alone, but should experiment to find others which will answer his purpose as well. The student should also provide himself with a supply of artgum erasers for cleaning his sketches and the edges of the finished drawing.

Pointed Cork.—In the right-hand end of the charcoal holder of Fig. 1, 6 is placed a pointed cork. This cork can be prepared from almost any cork bottle stopper, but should be chosen from one that is comparatively free of knots or hard areas. The smaller bottle stoppers are best for this purpose. This cork drawing instrument serves similarly to an ordinary paper stump but is superior for softening lines and blending small areas on paper or Ross stipple board.

Chamois and Blunt Cork.—Fig. 1, 7 shows another charcoal holder, the left-hand side of which has been mounted on a piece of chamois wrapped around a small bit of the same material to form a pad. This pad is used to clean up areas of the final drawing when they are found to be too dark. On the right-hand end of this charcoal holder (Fig. 1, 7) is mounted a piece of cork that is round in shape rather than pointed. It is used for softening larger dark areas on the final drawing.

Engraving Tool or Scratcher.—Fig. 1, 8, is undoubtedly one of the most important of the drawing instruments. It is an *engraving tool* made of wood through which passes a flat piece of a very good grade of steel. One side of the wood and steel has been ground flat on an emery wheel, as seen on the right-hand side of Fig. 1, 8a. The point is curved as seen in part 8 of the same

*Manufactured in Newark, N. J., which may be obtained from the F. Weber Company, Philadelphia, Pa.

figure. It is then ground on a fine carborundum flat stone, and polished further on a *hard* Arkansas oil stone. The point must be kept at razor sharpness at all times by means of the Arkansas oil stone, without ever using the emery wheel or carborundum stone a second time. All high lights on the finished drawings are scratched out or etched out of the chalk-surfaced stipple board with this tool.

Use of the Engraving Tool.—Thin lines or pin-point high lights may be made by holding the engraving tool vertically; as the angle to the surface is decreased, a broader line may be drawn. The engraving tool or *scratcher*, as it is called by medical artists, is held between the index and second fingers and guided by the thumb rather than being held as one does a pencil (see Fig. 3). However, use all tools in the manner that is most suitable to you as an individual and work with the kind of tools that you can use best.

FIG. 3.—The method of holding the engraving tool for scratching out high lights in drawings on Ross stipple board. This tool must be kept at razor sharpness, otherwise harsh ragged lines will result.

Charles Dana Gibson stated in one of his lectures that many art students ask him what particular make of pen point he uses in making his pen-and-ink drawings. His answer was that he uses any kind he finds suitable to draw with. After all, it is the artist who uses the instrument rather than the instrument that makes the drawing. However, certain instruments are better for specific purposes.

Unless the scratcher is kept sharp it not only becomes cumbersome to work with, but invariably makes broken, irregular high lights or white lines that reduce the quality of the drawing. The further use of these tools will be described fully when we actually begin the making of a scientific illustration.

Pencil Dust or Crayon Sauce.—The final drawing is worked up on stipple board with carbon pencils or crayon sauce that is applied with brushes. Crayon sauce may be prepared by sandpapering the center or so-called lead of the *Camé* No. 3 pencil. This pencil serves best for this sauce since it is of the right

softness. Harder pencils give a dust that does not grip or stick to the stipple board quite so readily. This dust or sauee may be saved in a small box, such as those in which the more expensive cigarettes are packed. An ideal way to collect it is to mount an ordinary sandpaper pad that is purchased in art stores (for sharpening charecoal) on an angle and to a side in one of these boxes. When the Conté pencil is pointed on the pad the dust slides from the pad into the box. In this way the artist kills two birds with one stone; he points his pencil and saves the dust which is later applied to the drawing. It might be well to bear in mind that no other pencils but the Conté No. 3 should be pointed in this box, as

Fig. 4.—Brushes used for the pencil dust or crayon sauee technique. No. 1 is a large camel's hair or sable blending brush. Nos. 2, 3, and 4 are red or black flat sable brushes for applying tones. The numbers written on the handles of the brushes denote their sizes. This illustration is reproduced the exact size of the original brushes. (From the catalog of F. Weber Co.)

only the soft Conté No. 3 dust is suitable for applying with the brushes. Under no conditions should an ordinary lead pencil be sharpened on the pad, because carbon pencil lines will not stick to the surface of the paper over ordinary pencil lines but will slide smoothly over them and leave no mark at all. A mixture of these dusts will only lead to difficulties. Should the artist not care to save this Conté dust in the manner described, he will be able to purchase it already prepared under the name of crayon sauee. However, he will find that the numerous necessary sharpenings of his Conté pencil will provide an ample supply.

Brushes.—There are four brushes used for applying this Conté dust. Fig. 4, 1 shows a fair-sized sable blending brush. This is suitable for applying an even tone over the entire surface of the paper. Darker tones may be put in with one of the other three brushes seen in Fig. 4, 2, 3, and 4. The smaller brush is used for fine work and the others for covering larger masses. The brush shown in Fig. 4, 3 will be the one that is used most.

Obtaining Dark Tones.—When the drawing is practically finished, the student will find that there are areas which must be made darker when the stipple

board will not take a tone of sufficient blackness. This can be accomplished by pouring (not atomizing) alcohol on the drawing and then draining it off at a corner back into the bottle. After the alcohol has drained off sufficiently to lose its glossy, wet appearance, more pencil dust can be applied with the brush. The stipple board thus treated with alcohol permits darker tones. However, this should not be done until the drawing is practically finished, as any erasing thereafter becomes more difficult. The alcohol has a tendency to harden the chalk surface of the stipple board. Never pour alcohol or fixative on a charcoal drawing. It is necessary to apply the alcohol or fixative to charcoal drawings with an atomizer.

After this alcohol treatment there may be points that still need to be made darker. This can be accomplished with pen and India ink; however, bear in mind that the less it becomes necessary to apply ink, the better the drawing is likely to be. Work continuously with pencils, crayon sauce, and brushes until you can see no other points to improve, then apply the ink to points that you find impossible to make darker with the pencil or crayon sauce. Any number of applications of alcohol may be applied without harming the drawing, except for erasing. When entirely finished, the drawing may be fixed with ordinary alcohol fixative (for charcoal drawings) that has been diluted with three parts of alcohol.

Summary of Materials.—The following is a summary of the materials used in making drawings in pencil dust on Ross stipple board:

An ample supply of thin drawing paper or a good grade of typewriting paper. Some of the sheets should be twice typewriting paper size for large drawings.

Ross stipple board No. 00 dull.

A supply of heavy cardboard for mounting, at least 14 ply.

Water paste, rubber cement, or dry mounting process for mounting.

One engraving tool or scratcher.

Conté No. 3 pencils.

Crayon sauce.

Wolff pencils—BB, B, HB, and H.

Two charcoal holders.

Cork for stumps.

A piece of chamois.

Three flat red or black sable brushes, $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ inch wide.

One blending brush about 1 inch wide.

Nigrivorine erasers.

Artgum erasers.

THE PENCIL DUST TECHNIQUE

As the antiquated axiom goes, "Rome wasn't built in a day," so it is with developing the ability to draw. We do not acquire perfection in the production of scientific illustrations overnight. For this reason, the study of the pencil dust technique should be started with comparatively simple subjects, such as a few Malaga grapes, a rubber tube or ball. Before accepting these as simple

subjects let us first study them carefully. There are high lights, reflected lights, and shadows to be considered. Grapes are semitransparent or translucent. This effect of transmitted light is not easy to obtain on paper, therefore one's first drawing should be undertaken with great care and a determination to produce a satisfactory illustration.

Fig. 5.—A pencil dust drawing of two balls or spheres.

Fig. 6.—A pencil dust sketch of a white rubber tube. Such practice drawings are made in an effort to learn to produce the effect of the third dimension.

When a drawing is copied from a reproduction, it should be enlarged many times, at least to a convenient working size. When drawings in tone are copied, they should be copied from the original drawings if possible, though it is far

better to work from the actual subject. For this reason, simple subjects easy to obtain are mentioned. Where it is not possible to obtain the same subject, a similar one will serve. For instance, white marbles or large clear glass beads could take the place of grapes. The drawing of grapes, marbles, or beads develops a dexterity in drawing the cysts that are so often present in pathologic specimens. While some of these subjects will be quite simple and seem to possess little bearing on scientific illustration, they have been chosen for a definite purpose. The training received in drawing them will be useful when actual scientific subjects present themselves.

Make a careful line sketch of the model with a Conté No. 3 or Wolff BB pencil. This sketch may be the same size as the subject. It is best to try to make this, as well as the subsequent sketches, in line rather than graded tones, because this helps to develop a feeling for lines and how their placing, running directions, and curves can determine various ideas of modeling and shading. This rule should be followed in making all scientific drawings for transfer. Such

Fig. 7.—A small drawing of an ovarian cyst. This type of drawing shows one of the first subjects a student should undertake in developing a technique for illustrating pathologic specimens. Many principles he should have learned from drawing spheres, depressions, raised areas, and grapes apply to the making of such an illustration.

practice is invaluable when it becomes necessary to make pen-and-ink drawings which are generally done in line only. There is a dry brush and India ink technique used quite often by commercial artists, but I believe that at present it is not well suited to scientific illustration. However, there is no reason why some excellent draftsman should not be able to develop a brush and ink technique suitable for this purpose.

Transferring.—After this line sketch is well developed, transfer it as previously described. It is this transfer which is to be worked into the final drawing.

Developing the Pencil Dust Drawing.—First, carefully outline the subject with a Wolff BB pencil. Do not make these outlines too heavy, as it must be remembered that they are eventually to be blended into the tones of the body of the drawing. A general tone now may be applied to the entire surface of the paper with the blending brush. Dip the brush in your box of crayon sauce

and then wipe it off on the chamois pad for that purpose. Lightly brush over the entire surface of the drawing, thus giving it a general tone of about the shade you consider the greater part of the original to be. Using this as a key, pick out the high lights with the nigrivorine eraser and apply the darker tones with the flat sable brushes.

Fig. 8.—Two views of a single pathologic specimen showing the method of placing it in its natural surrounding structures as a means of orientation. Many principles learned in the simpler drawings make it possible to produce a more complicated drawing as illustrated above.

No hard and fast rules are set down for the remainder of the work of developing the drawing. The student should work in the way which suits him best. The following directions are no more than suggestions of how to use the materials for the pencil dust technique. Some students prefer to pick out the high lights and lighten the areas that are lighter than the general tone. Others start right in with the brushes to obtain the darker gradations. Either method is acceptable.

Fig. 9.—In illustrating a surgical procedure the operative technique should be developed step by step. For example, this illustration shows the first step in an operation for the treatment of nephroptosis. The caption published under this figure read as follows. "A modified hockey stick incision. The intercostal muscle is exposed in the upper end of the wound. An adequate exposure is obtained with a maximum of consideration to anatomic details." (From the Bulletin of the School of Medicine, University of Maryland.)

Working From Light to Dark.—Find the definite high lights, which can be little more than points. Erase these from the general tone with the pointed eraser. Larger areas may be wiped out with the mounted chamois. If these areas are to be made still lighter, they may be erased by lightly touching or gliding the pointed eraser over the surface of the paper. Definite points of light may be etched or scratched out with the engraving tool. However, this

should not be done until the drawing is well modeled with the brush and eraser. If the engraving tool is used too soon, the drawing may lack depth of modeling. These are terms employed to express the illusion of the third dimension on a flat surface such as drawing paper. After the drawing is well modeled, the engraving tool is used to etch out minute points of light and to lighten small

Fig. 10.—Another step in the development of the same surgical procedure. The caption under this figure read as follows: "A method of placing sutures in the renal capsule. These sutures may vary in position as desired. The pedicle and ureter are freed of connective tissue. The anterior surface of the kidney is shown and the ureter is pulled medially." (From the Bulletin of the School of Medicine, University of Maryland.)

areas by gliding the instrument over the paper. If this tool is of razor sharpness and handled lightly, it will remove only the tops of the tiny raised areas of the stipple board and create an additional tone that will improve the drawing as a whole. The best illustrations have a full range of tone from the lightest light to the darkest dark, with numerous graded tones between.

A brush of medium size that has been dipped in the crayon sauce may be used to blend carefully and lightly in the shades of tones on the shadow side of

the drawing. Bear in mind that space must be saved for the reflected lights and that the tone is darkest next to these reflected lights. After these tones are shaded in to the best of your ability, take the pointed cork and soften the outlines that were drawn in the beginning. Be careful not to let the tone which is spread by the cork come too far over into the reflected lights, or the lighter areas, as a wide line. Should this happen the overlapping tone may be removed by the pointed eraser.

Fig. 11.—In this step of the procedure, the free ends of the capsular sutures are brought out through the intercostal muscle above the twelfth rib before the kidney is drawn into place. (From the Bulletin of the School of Medicine, University of Maryland.)

Use of Drawing Instruments.—As the drawing develops use the instrument which suggests itself. When a point or area is too dark, use the eraser, chamois, or engraving tool to lighten it. When it is too light, use the cork, brushes, or pencils to darken it. It is a constant alternating from one instrument to another and a careful working with them that eventually produces a finished drawing.

Study the high lights, reflected lights, shadows, and translucencies of the subject and try to duplicate them in the drawing. Translucency may be difficult to obtain but by constant effort it can be accomplished.

FIG. 12.—A further step in the same procedure. The caption under this figure read as follows: "An illustration of the kidney in the desired position. Overcorrection and dependent drainage are obtained. The fatty capsule supplies secondary support." (From the Bulletin of the School of Medicine, University of Maryland.)

You will find that the spotted effects so often seen on fresh pathologic specimens can be produced by just touching the surface of the stipple board with the pointed eraser and cork. As you work, such ideas of obtaining different effects suggest themselves.

Developing the Darks.—After you have worked the drawing to a point where the stipple board will not take any darker tones, flow the alcohol over the mounted drawing and allow it to drain back into the bottle from a corner. Be sure that the entire surface of the paper is covered with alcohol, otherwise a line

may form between the covered and uncovered surfaces. As soon as all indications of wetness have disappeared, a second coat of crayon sauce may be applied where necessary to obtain darker tones.

Fig 13.—The final illustration in the surgical technique previously described. The caption under this figure read as follows: "A diagrammatic posterior view of a hypothetical case and the degree of correction possible." (From the Bulletin of the School of Medicine, University of Maryland.)

If there are areas that are still to be made darker, this may be accomplished by passing the point of the Wolff BB or Conté pencil lightly over them. In such a case do not bear hard enough on the pencil to press into the paper or to leave a microscopic mound of carbon at the end of a pencil line. It is better to go over the area again and again until the desired tone is produced. The final dark touches to the drawing may be done with pen and India ink. This should be applied sparingly, otherwise it may be conspicuous to the point of affecting the quality of the drawing.

Fixing Pencil Dust Drawings.—After you have worked on the drawing until nothing further suggests itself, it should be made permanent with a weak fixative of one part fixative to three parts of alcohol.

Fixative of normal strength can be made by dissolving 2 ounces of gum mastic in 8 ounces of alcohol. For pencil dust drawings this should be diluted to a point where it will leave no gloss on the stipple board after it is dry. This can be done by adding three parts of alcohol to one part of fixative.

Shellac fixative can be made as follows: Dissolve $\frac{1}{4}$ pound of dry white shellac in a quart of alcohol. Shake well every few days until the shellac is completely dissolved, then let it settle for ten days and pour off the clear yellow liquid above the shellac that has settled to the bottom of the container. Be careful not to allow any of the sediment to mix with the clear solution. For pencil dust drawings this should be diluted with about six parts of alcohol.

It is best for the fixative to be no stronger than necessary to keep the pencil dust from smudging or coming off the board. While drawings can be worked on after fixing, it is better to develop them as far as possible before fixing.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

MENINGITIS, Pneumococcal and Influenzal, Treatment of, With Sulfapyridine and Its Sodium Salt, Neal, J. B., Appelbaum, E., and Jackson, N. W. J. A. M. A. 115: 2055, 1940.

The authors present a series of 30 cases of pneumococcal meningitis with 10 recoveries and 29 cases of meningitis due to *H. influenzae* with 14 recoveries treated with sulfapyridine, its sodium salt, or both. A specific serum was usually employed as well. However, they believe, in view of previous experience, that the lower case fatality in both forms of meningitis is attributable largely to this form of chemotherapy.

SMEGMA BACILLUS, Differentiation of Tubercle and, Bent, M. J., and West, H. D. Am. Rev. Tuberc. 42: 815, 1940.

The disappearance of color in cultures of smegma bacilli grown on Petraguani's and on Petroff's media containing malachite green can be used to differentiate these organisms from tubercle bacilli which are not capable of producing the change in these culture media.

The color change results from a tautomeric shift of the dye molecule to the colorless color base of malachite green because of increased alkalinity. The increased alkalinity is due to the greater production of ammonia by the smegma bacilli.

Autolysis of smegma bacilli with the production of ammonia is probably an important factor.

BONE, Giant Cell Tumor of, Jaffe, H. L., Lichtenstein, L., and Partis, R. B. Arch. Path. 30: 993, 1940.

A conception of the giant cell tumor of bone has been developed which can be briefly summarized as follows: The giant cell tumor of bone is not as common or as miscellaneous a lesion as it has generally been supposed to be. Cases of medullary fibroma or osteofibroma of medullary xanthofibroma or xanthogranuloma, and of certain peculiar forms of medullary chondroma, for instance, are sometimes misclassified under the head of giant cell tumors—notably as representing supposed variants of the latter. The authors deprecate this tendency and hold in particular that cases classed under the head of "osteitis fibrosa or spindle cell variant," "xanthic variant" or "chondromatous variant" of giant cell tumor actually represent misclassified cases of these other, independent conditions. They have frequently made such misclassifications. Furthermore, they feel that the resemblance between the so-called "brown tumors" of hyperparathyroidism and certain epulides, on the one hand, and genuine giant cell tumors, on the other, is only superficial and is not based on any pathogenetic relationship.

The authors interpret the giant cell tumor of bone as a neoplasm of a definite kind, arising apparently from the undifferentiated supporting connective tissue of the marrow and clearly delimitable on the basis of its cytologic details. In essence, it is composed of a more or less vascularized network of spindle-shaped or ovoid stromal cells and multinuclear giant cells in certain particular proportions and arrangements. The tumor shows but little collagenous differentiation of its stroma and almost no evidence of ossification. However, there are differences between individual giant cell tumors, particularly in respect to aggressiveness, based mainly on differences in stromal cell detail. On the basis of these differences, we have found it expedient to subclassify giant cell tumors into three grades.

Those which are classed under grade I are the least aggressive ones, in which the stromal cells, though abundant, are not compacted and do not exhibit any appreciable atypism. The tumors of grade II manifest cytologically a very compact cellular stroma, showing definite evidences of atypism, tend strongly toward recurrence, and in some cases eventually undergo malignant transformation. Those of grade III represent the small group which possess a sarcomatous type of stroma, are frankly malignant and metastasize. The malignant giant cell tumors are characterized microscopically by the presence of abundant, compacted stromal cells appearing in whorled arrangement and uniformly showing signs of atypism.

From the clinical point of view this study has shown that a genuine giant cell tumor is not likely to develop in any person below the age of 20. In connection with the interpretation of the roentgenographic findings, it is pointed out that, despite the common opinion, there is no such thing as a "typical" or a "characteristic" roentgen picture of a giant cell tumor. It is maintained further that "blind" irradiation based on an unverified roentgenographic diagnosis is usually not justifiable and that a biopsy should be performed on a bone lesion suspected of being a giant cell tumor to establish the diagnosis definitely before therapy is undertaken. The treatment of a giant cell tumor of bone should be guided by the idea that this lesion (considered independently of its supposed variants) is, on the whole, a more serious one than it has usually been supposed.

SULFATHIAZOLE in Blood and Urine, Sunderman, F. W., and Pepper, D. S. Am. J. Med. Sc. 200: 790, 1940.

Applying methods for the analysis of sulfanilamide in whole blood to the measurement of sulfathiazole, the authors have found that recovery of sulfathiazole in whole blood averages approximately 86 per cent of the theoretical. This diminution in the recovery was shown to occur during protein precipitation. Employing serum instead of whole blood, loss of sulfathiazole is considerably less, averaging only about 3 per cent. For this reason, the authors feel that analysis for sulfathiazole should be made in serum instead of whole blood. A procedure for analysis in serum is suggested in which an arbitrary correction for the loss is made in the final calculation.

Since both sulfathiazole and its acetyl derivative are about twice as soluble in urine of pH 7.6 as in urine of pH 5.6, it may be inferred that when crystalline concentrations owing to sulfathiazole therapy threaten, an effort should be made to keep the urine alkaline and to secure a large urinary volume.

The method for serum follows: Two milliliters of serum obtained from centrifuged clotted blood are run into a 25 ml. volumetric flask containing 10 ml. of 8 per cent trichloroacetic acid. After shaking thoroughly to keep the precipitate finally divided, the solution is diluted to the mark with distilled water. The contents are mixed and allowed to stand for twenty minutes; then filtered through Whatman No. 44 paper to obtain a clear, colorless filtrate. Ten milliliters of the filtrate are diazotized at room temperature with 1 ml. of 0.1 per cent freshly made solution of sodium nitrite. The solution, after standing for three minutes, is treated with 1 ml. of 0.5 per cent solution of ammonium sulfamate. After mixing thoroughly, 5 ml. of dimethyl-alpha-naphthylamine coupling reagent are added; the tube is stoppered, inverted once, and allowed to stand for ten minutes.

Comparisons of color development are made by means of a colorimeter (or photoelectric cell device), utilizing sulfathiazole standards of appropriate concentrations carried through the same procedure as with the unknown. It is important that the solutions be well shaken before placing them in the colorimeter cups to eliminate small gas bubbles that may be present. (The gas is presumably nitrogen formed by the destruction of HNO_2 with $\text{NH}_2\text{SO}_2\text{NH}_2$.) The authors employ a colorimeter (Bausch & Lomb) having an attachable lamp. The eyepiece of the colorimeter is fitted with a No. 74 Wratten filter. Standards of appropriate concentrations are made from a stock solution of sulfathiazole containing 200 mg. per liter. It is convenient to have prepared standards with concentrations of sulfathiazole of 0.2, 0.4, and 0.8 mg. per 100 ml., respectively.

Calculation:

Reading of Standard

Reading of Unknown \times mg. of Sulfathiazole in Standard \times Dilution factor \times Correction factor = mg. per 100 ml. Correction factor = 1.03.

Recovery of sulfathiazole from protein-free urine is practically quantitative. The procedure for serum may be applied to urine determinations disregarding the correction factor. It is preferable that appropriate dilutions of urine be made so that sulfathiazole concentration in the diluted urine is between 5 and 30 mg. per 100 ml.

MENINGITIS, Pneumococcic, Treatment of, Rhoads, P. S., Hoyne, A. L., Levin, B., Horswell, R. G., Reals, W. H., and Fox, W. W. J. A. M. A. 115: 917, 1940.

In a series of 22 consecutive cases of pneumococcic meningitis treated by the authors with the combined use of sulfanilamide or sulfapyridine (and its sodium salt) and specific antipneumococcus rabbit serum there were 7 recoveries.

In the period covering these cases, more patients were admitted to the Cook County Hospital with pneumococcic meningitis than with meningococcic meningitis. The old teaching that purulent meningitis should be treated as meningococcic meningitis until proved otherwise is entirely outmoded. A vigorous search for the etiologic agent must be started at once and pursued until the organism is determined. Pending that time, sulfapyridine by mouth or its sodium salt intravenously should be given in large doses, unless hemolytic streptococci are strongly suspected, in which case sulfanilamide may be the better chemotherapeutic agent.

The best prognosis in cases of meningococcic meningitis is in so-called primary cases, i.e., those unassociated with other demonstrable pneumococcic lesions. The worst prognosis is in those cases associated with pneumococcic endocarditis and/or extensive pneumonia.

In addition to vigorous chemotherapy and serum therapy, surgical drainage of focal lesions, care to maintain an adequate fluid and caloric intake, and occasionally blood transfusions, are of the utmost importance.

RECTUM, Prognosis in Carcinoma of, Broder, A. C., Buie, L. A., and Laird, D. R. J. A. M. A. 115: 1066, 1940.

A total of 432 resected specimens of carcinoma of the rectum were graded according to Broder's method and grouped according to Duke's method of classification. The distributions of grade and class were studied in comparison with other investigations and also in relationship to survival after operation. On the basis of the entire study, certain conclusions were reached:

1. The presence or absence of mucus loses importance as a guide to prognosis if histologic grading is done by Broder's method.
2. Tumors of higher grades are more rapid in growth, and their metastases cause the death of the patient earlier than those of lower grades.
3. The classification of the lesion according to the method of Duke is also correlated with postoperative life; the higher the class, the less the percentage survival.
4. A combination of Broder's grading and Duke's classification yields a prognosis of survival more accurate than either method taken separately.

HYPERTENSION and the Surgical Kidney, Braasch, W. F., Walters, W., and Hammer, H. J. J. A. M. A. 115: 1837, 1940.

One hundred and fifty approximately consecutive nephrectomies were studied. These cases were representative of severe unilateral renal damage.

Hypertension was not a common finding in the clinical picture in this group.

Vascular changes, which have been considered to be causative factors in the production of hypertension, were present in a high percentage of the cases.

Elevation of blood pressure readings in these cases was not the rule, even in chronic pyelonephritis. Nephrectomy was not followed by appreciable reduction in blood pressure readings before operation.

The exact etiologic factor in renal (ischemic) hypertension is as yet unknown. The pathologic and anatomic elements seem less important than an as yet unknown physiologic element.

BIOPSY, Testicular, Its Value in Male Sterility, Charny, C. W. J. A. M. A. 117: 1429, 1940.

The testis, with the serotal skin taut, is held in the operator's left hand. After application of an antiseptic, a portion of the skin overlying the anterior surface of the testis is infiltrated with 1 per cent procaine hydrochloride. An incision about 1.5 cm. long is made through the skin and carefully carried through all the fascial layers until the parietal layer of the tunica vaginalis is opened. This is signalized by the escape of serous fluid and the appearance of the glistening visceral layer of the tunica vaginalis. The latter and the tunica albuginea are nicked with a small scalpel. Gentle pressure on the testis now serves to extrude a small bead of tissue, which is cut off with a curved iridectomy scissors. The testicular incision need not be sutured. The skin is closed with two interrupted catgut sutures and a collodion dressing is applied. The patient may return to his former duties the following day, wearing a suspensory for a day or two. The specimen of tissue is preserved in Bouin's solution, mounted in paraffin for section, and stained by hematoxylin eosin.

Testicular biopsy is a simple, innocuous procedure, as shown by its application in 40 infertile patients without a single mishap.

Testicular biopsy is not only a definite diagnostic aid in differentiating between obstructive and nonobstructive semen defects but serves a prognostic function as well.

When performed before and after treatment, testicular biopsy yields the most direct evidence of the efficiency of the therapeutic agent employed.

PNEUMOCOCCIC INFECTION, Changes in the Number of Circulating Leucocytes in Relation to Spontaneous Recovery From, Fleisher, M. S., and Rich, G. T. Arch. Path. 30: 843, 1940.

The change (relative increase or decrease) of the total number of leucocytes and of the number of neutrophils per cubic millimeter of the circulating blood of the guinea pig twenty-four hours after infection with type I pneumococci bears a positive relationship to the spontaneous death or recovery of the animal. Even at six hours after infection this relationship is suggested or is evident. This positive relationship can be observed when death or recovery is postponed for more than twenty-four hours subsequent to six-hour or twenty-four-hour counts. Study of the response of animals to a nonspecific irritant suggests the possibility that this early reaction of the leucocytes is at least in part an inherent physiologic adaptation of the animal.

BLOOD VOLUME and Extracellular Fluid Volume in Infants and Children, Robinow, M., and Hamilton, W. F. Am. J. Dis. Child. 60: 827, 1940.

Blood volumes of newborn infants averaged 98.3 \pm 8.7 c.c. per kilogram of body weight. The relative plasma volumes varied inversely with the hematocrit reading. A tentative explanation for this phenomenon is given.

"Extracellular fluid volumes" were calculated from the dilution of intravenously injected sodium sulfocyanate. These volumes increased with age if calculated on the basis of body surface but decreased if calculated on the basis of body weight.

Extracellular fluid volumes were found to be large in nephritic edema and in malnutrition. Low values were found in obesity and in dehydration.

Histamine shock in dogs did not change the concentration of sulfocyanate in plasma. The fluid of edema in acute nephritis is apparently entirely extracellular.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, 201 West Franklin Street, Richmond, Va.

Diagnosis and Treatment of Menstrual Disorders and Sterility*

THIS book is a well written, thorough summary of endocrine functions in gynecology which is easy to read and interesting. It is written more from the clinical than from the didactic standpoint, and thus is of practical benefit to the practitioner. The authors take up the entire field of menstrual disorders very thoroughly as to diagnosis and treatment, and include sufficient aspects of anatomy, etiology, and pathology to present a complete picture. There is also a short but comprehensive summary of the normal physiology of the menstrual cycle. The subject of sterility is thoroughly taken up as to etiology, diagnostic study, and treatment.

The book is well illustrated and contains tables illustrating differential diagnosis. There is a good bibliography at the end of each chapter and a well-prepared index.

Synopsis of Materia Medica, Toxicology, and Pharmacology†

EXCEPT for the dimensions of the volume this can hardly be considered a synopsis. With over 600 pages printed in small type, it is a very comprehensive pharmacology. The book is small, and therefore, might be termed a handbook. Otherwise it is an excellent reference work on pharmacology.

It takes up the subdivisions of the subject in logical order, starting with basic principles, then materia medica, and prescription writing, followed by toxicology.

To the reviewer this seems to be a very logical approach, and one which is usually not followed since most of these subjects appear in an appendix at the end of a book. Obviously, these are phases that could well be mastered by the student before starting with the actual basic considerations of the action of drugs.

In the body of the book, drugs are grouped in accordance with the localization of their action, whether it be in the skin, central nervous system, the peripheral nervous system, muscle, the urinary tract, etc. Final chapters deal with vitamins, serums, vaccines, hormones. The sulfonamide compounds are grouped with several other drugs in a final miscellaneous chapter.

The American College of Physicians‡

THIS volume is unique in that it presents a complete and accurate history of one of our outstanding medical organizations from its birth in 1915 to the present time. The editor,

*Diagnosis and Treatment of Menstrual Disorders and Sterility. By Charles Mazer, M.D., F.A.C.S., Assistant Professor of Gynecology and Obstetrics, Graduate School of Medicine, University of Pennsylvania; Gynecologist to the Mount Sinai Hospital, New York City. 1940. 108 pages. \$6.50. Paul B. Hoeber, Inc. London, 1941.

†Synopsis of Materia Medica, Toxicology, and Pharmacology. For Students and Practitioners. By Ramon Davison, B.A., M.Sc., Ph.D., M.B., Assistant Professor of Medicine, University of Arkansas, Little Rock. Cloth, pages 600. The C. V. Mosby Company, St. Louis, 1940.

‡The American College of Physicians. Its First Quarter Century. Historian William C. C. Morgan, M.D., LL.D., Sc.D., M.A.C.P., Fellow of the American College of Physicians, Secretary-General (1929-32), Secretary-General (1932-37), of the American College of Physicians; Professor of Medicine, Georgetown University School of Medicine, Washington, D.C. 1940. 275 pages. \$2.00. American Medical Association, Chicago, Ill.

Doctor William Gerry Morgan, is peculiarly qualified for the assignment of chief historian. He became a member in 1916, and has closely followed the vicissitudes and triumphs of the College since that time, holding several offices of trust and responsibility during the formative period of the Society, as well as in later, more sanguine years.

The History is conveniently and logically divided into two parts. Part One consists of chapters on: "The Founding of the College"; "The Presidents of the College"; "Other Officers," including The Secretary-Generals, The Treasurers, Editors of the Journal, Chairmen of the Board of Governors and The Executive Secretary from the pen of Doctor William Gerry Morgan; "The Constitution and By-Laws"; "Financial Record of the College" contributed by Edward R. Loveland; also "The Publications of the College"; "The American Board of Internal Medicine"; "My Recollections of the Period, 1925-29"; "The Story of Recent Years"; by Doctors Maurice C. Pineoffs, Walter L. Bierring, Charles F. Martin, and James Alexander Miller, respectively. This section contributes a number of short biographical sketches of outstanding American physicians. Part Two, "The Chronology," presents, in documentary form, abstracts from the minutes of the meetings of the Board of Regents and the Board of Governors. A final chapter outlines the present objectives, activities, administration, and requirements of admission to the College. The preface is splendidly written by a former President and present Secretary-General, Doctor George Morris Piersol.

A comprehensive, quarter century history of The American College of Physicians must necessarily contain a great deal of the worth-while history of American medicine. Therefore, this work should be of vital interest to all who practice that art in this country.

The Pharmacological Basis of Therapeutics*

THIS is a major contribution to the literature of pharmacology. It will undoubtedly soon assume a position as one of the three leading textbooks on the subject. The sequence of presentation is new. The drugs discussed are brought up-to-the-minute and include the latest sulfonamide compounds, endocrine preparations, and the newest anesthetics and hypnotics. The discussion of pharmacologic action is broadened in that there is more than the usual description of clinical action in addition to effects on experimental animals. The volume will find a place not only as a textbook but also as a general reference manual.

*The Pharmacological Basis of Therapeutics. A Textbook of Pharmacology, Toxicology and Therapeutics for Physicians and Medical Students. By Louis Goodman, M.A., M.D., Assistant Professor of Pharmacology and Toxicology, Yale University, School of Medicine; and Alfred Gilman, Ph.D., Assistant Professor of Pharmacology and Toxicology, Yale University, School of Medicine. Cloth, pages 1383, \$12.50. The Macmillan Company, New York, 1941.

CORRESPONDENCE

The Editor,

JOURNAL OF LABORATORY AND CLINICAL MEDICINE.

Owing to the fact that the male partner in marital infertility is of late being more acutely observed, reports emanating from competent observers show that the husband is at least responsible for sterility just as frequently as is his mate. With this new swing toward placing the responsibility upon the male in certain instances of necrozoospermia, a word of caution should be interposed.

If repeated semen analyses, when correctly performed, show no evidence whatsoever of the presence of spermatozoa, the basic cause for infertility may be placed directly upon the male. However, within the past few years I have seen the male blamed in numerous instances because of an erroneous diagnosis of total necrozoospermia. Although an ejaculate is sometimes encountered with all the spermatozoa motionless (dead), true necrozoospermia within the male genitals is a rarity. Sperms can be easily killed by a number of external factors soon after ejaculation, giving the false impression that they were dead before ejaculation. I believe that this occurs more frequently than is usually believed.

I have collected 17 illustrative patients (four of them physicians), in whom the seminal fluid had been previously tested by different examiners. In each instance, the husband had been informed that many sperms were found but that all were dead. Since these men had been found deficient, their spouses were not examined. Following the semen findings, the men were encouraged either to submit to some form of injection therapy to "improve" their sperms or to adopt a child or to resort to artificial donor inseminations.

In my examinations the semen in *every case* presented living, motile spermatozoa. Although six men showed evidence of spermiatic deficiency, not one of them had specimens that contained less than 16,000,000 living spermatozoa per cubic centimeter of semen. Eleven were found to fit within the normal range of male fertility, and in these it was urged that the etiology of the barren marriage be sought for in the female partners. Upon checking back at the earlier diagnosis of total necrozoospermia, it was shown that in each instance there was some error either in the collection or in the transportation of the semen, prior to examination. The death of the spermatozoa could, therefore, be definitely traced to some external factor following ejaculation.

By far the most common cause of death of spermatozoa after ejaculation was the condom method of semen collection. It has been repeatedly shown within the past few years that the condom should be discarded as a method of collection of semen for analytical purposes, because the chemical substances with which the rubber is treated are drastic spermicides. Not only do the substances

used in the manufacture of rubber act as spermicides, but also in many instances condoms are treated with chemical dusting powders, possible contraceptive substances, and other materials deleterious to sperm life. The use of the washed condom should also be discontinued since it is not ideal for sperm life and rubber decomposes when lubricated.

Another means used to cause neerozoospermia was the condom specimen placed in hot water. The patient in his zeal to follow instructions to "keep the specimen warm" placed the condom in a thermos bottle containing hot water which could almost scald. This, in spite of the now accepted fact that spermatozoa fare poorly in heat and do well at temperatures *below* that of the body. Spermatozoa live more than twice as long in a test tube at ordinary room temperature than when kept warm at body temperature.

Other causes of sperm death were contaminants from glass receptacles. In one instance, the patient was given a container supplied by the city health department for use in collecting sputum for acid fast studies. The patient ejaculated into this container and noted a strong odor of carbolic acid from the specimen jar. A few drops of phenol are added to these sputum jars as a preservative, and carbolic acid, even when dilute, is a strong spermicide. In another instance, I received a specimen in a container which smelled strongly of formalin. Of course, the sperm cells were motionless. In an attempt to be ultra-scientific one physician brought his own semen to be analyzed and added what he thought to be physiologic saline to the semen. All the spermatozoa were immotile. It was found that the supposed "physiologic saline" was not really normal saline but a rough approximation. Unless the concentration of saline is exactly that of normal body solution of salts, any slight variation will be hostile to sperm life. Furthermore, normal saline has no place in semen collection or analysis.

Ordinary tap water has recently been shown to be highly spermicidal. Spermatozoa die immediately when exposed to plain water. All receptacles should be absolutely dry when used for semen collection.

I suggest a simple method for collection of semen. Although it may not be the most aesthetic, it is the most exact and scientific method. After the male has refrained from intercourse for four or five days, he appears at the examiner's office. He carefully washes his hands and genitals with soap and water. Then the hands and penis are thoroughly rinsed a number of times with tap water to remove all soap. The hands and genitals are dried with a clean towel. He urinates, to free the urethra from possible soapy contaminants. A specimen is then obtained by ejaculation into a clean, sterile, dry, wide-mouthed glass receptacle (either a wide specimen jar or an ordinary glass tumbler). None of the ejaculate is lost. The semen remains in the glass receptacle at room temperature for ten to fifteen minutes, to liquefy and become mucolyzed. It is then ready for examination.

PROGRESS

RENAL ASPECTS OF EXPERIMENTAL AND CLINICAL HYPERTENSION*

A. C. CORCORAN, M.D., AND IRVINE H. PAGE, M.D., INDIANAPOLIS, INO.

ESSENTIAL and malignant hypertension were separated from the renal hypertension of Bright's disease by the accurate clinical and pathologic observations of Allbutt, Janeway, Volhard, Keith, and others. The intuitive concept of a renal origin of all, or at least of most, syndromes of increased arterial pressure was discarded because of (a) the manifest differences in clinical course which separate Bright's disease from essential and malignant hypertension; (b) the characteristic differences of degree and kind of renal structural change in nephritis and hypertension; (c) the view that, in early hypertension, the kidney is structurally and functionally intact and that, therefore, it cannot be the origin of the disease.

While the first and second of these criteria are undoubtedly true, they do not in themselves establish the extrarenal origin of essential and malignant hypertension. The third criterion, which supposes the integrity of the kidney in hypertension, seems to be invalidated by recent observations on the structure and function of the kidney in hypertension. Since the supposition of an extrarenal pathogenesis of essential and malignant hypertension largely depends on this assumption, a renal origin of hypertension is, therefore, not excluded.

Goldblatt, Lynch, Hanzal, and Summerville¹ have established that a syndrome similar in many ways to essential and malignant hypertension in man may be produced experimentally in animals as the result of partial compression of one or both main renal arteries. Experimental hypertension of apparently identical character has also been obtained by compression of the renal parenchyma in the fibrocollagenous scar of perinephritis due to application of silk or cellophane.² This development of experimental counterparts of hypertension

*From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital, Indianapolis.

has prompted an upsurge of interest in the relation of the kidney to increased arterial pressure, which has led to new concepts of the pathogenesis and clinical physiology of both the experimental and clinical disease. These concepts and methods in which they find their application form the subject of this review.

ORIGIN OF EXPERIMENTAL HYPERTENSION

Hypertension produced by compression of the renal arteries or of the renal parenchyma has been widely regarded as the result of renal ischemia. In particular, it is attributed to ischemia of functional renal tissue, since widely devitalized kidneys do not function as sites of origin of experimental hypertension.³ Measurements of renal blood flow in uninephrectomized dogs made hypertensive by compression of the renal artery have shown a decrease which averaged 40 per cent and ranged from 18 to 63 per cent.⁴ Further, it has been widely observed that experimental hypertension is more severe and more often malignant when renal arterial occlusion is nearly complete.⁵

Some doubt was cast on the belief that renal ischemia as such is the cause of experimental hypertension by the observation that urea clearance was sometimes normal in experimentally hypertensive animals,⁶ since urea clearance in normal dogs parallels the rate of renal blood flow.⁷ The further observation that the renal clearances of phenol red, inulin, and creatinine were in some instances not altered during the induction or course of experimental hypertension added weight to this doubt.⁸ Indirect measurements of renal blood flow before and after compression of the renal artery in uninephrectomized dogs with single explanted kidneys have since shown that hypertension of moderate degree may be induced without any significant or lasting change in renal blood flow (Chart 1), while in some instances renal blood flow may be reduced without the occurrence of an increase in arterial pressure.⁹

The apparent paradox that compression of the renal artery sufficient to induce changes in the kidney which lead to hypertension need not always be associated with renal ischemia demands an explanation that depends upon a consideration of the mechanism of blood flow. Thus, it should be noted that the rate of blood flow is the product of *mean* arterial pressure and of peripheral resistance. If, with increased resistance, there is a corresponding increase of pressure, no reduction of flow need occur. In any case, a high degree of arterial occlusion is necessary in order to reduce mean arterial pressure and blood flow distal to the point of compression.¹⁰ It should also be observed that the initial effect of arterial compression is a reduction of pulse pressure distal to the point of clamping, while mean arterial pressure and, therefore, blood flow, remain unchanged. It follows from these principles that arterial compression, as by the Goldblatt clamp, will nearly always result in a decrease of pulse pressure distal to the clamp and, if the constriction is sufficiently intense, will be associated with a decrease of mean pressure and blood flow. However, if mean arterial pressure proximal to the clamp is simultaneously increased, and if the compression is not excessive, neither mean arterial pressure nor renal blood flow need be reduced by clamping.

The view that renal hypertension may occur in the absence of renal ischemia is supported by the observation that mean renal arterial pressure in some experi-

mentally hypertensive dogs is normal distal to the point of clamping.¹¹ It is at least unlikely that renal blood flow would be affected by clamping when mean arterial pressure was not. Of interest also are observations¹² which demonstrate that, following clamping of the renal artery, there is a tendency for renal blood flow, which initially had decreased, to return to, or toward, normal levels.

Chart 1.—Relation of mean femoral arterial pressure to total renal blood flow¹³ in an uninephrectomized dog before (Δ) and after (\blacktriangle) application of a Goldblatt clamp to the main renal artery. The wide variations in blood flow over a period of more than one year are accounted for by repeated adjustments of the degree of arterial constriction. Normal blood flow persisted during moderate hypertension.

If then, experimental renal hypertension may persist in the absence of renal ischemia, the decreased pulse pressure which follows clamping remains as a possible cause of the renal change that leads to hypertension. Experiments were, therefore, performed in which isolated dog's kidneys were perfused with blood under conditions which were as physiologic as possible. A clamp was gradually adjusted on the renal arteries to a point where pulse pressure was greatly reduced while renal blood flow was either unaffected or slightly decreased. Arterial pressure was then increased proximal to the compression so that both mean arterial pressure in the renal artery and renal blood flow remained within normal limits. Under these circumstances, the perfused kidney liberated renin, the so-called renal pressor substance, into the renal venous blood.¹³

It appears, therefore, that renal ischemia is not the necessary cause of renal hypertension, and the suggestion is made that intrarenal reduction of pulse pressure may be the exciting cause. However, it should be noted that those circumstances which excite experimental renal hypertension, possibly by reduction of pulse pressure, also, when applied with sufficient intensity, result in reduction of renal blood flow, so that the level of renal blood flow in experimental hypertension depends upon a balance struck between increased arterial pressure and increased renal arterial resistance.

The mechanism by which reduction of pulse pressure may lead to the establishment of hypertension is not clear. It is known that organs perfused in the absence of pulsatile flow speedily become edematous, and that their cells may lose their normal permeabilities to vital dyes.¹⁴ It is, therefore, conceivable that renal cells are normally impermeable to renin; this is evidenced by the absence of renin from normal renal venous blood. But reduction of pulse pressure increases renal cellular permeability so that renin escapes; this is supported by the presence of renin in the renal venous blood of hypertensive animals and man.¹⁵

If pulse pressure rather than blood flow is the determinant in the liberation of renin, it follows that renin must arise in some site normally exposed to a high pulse pressure, i.e., proximal to the glomerulus, and, probably, in an area in close relation to the afferent arteriole. Modification of the muscle cells of the afferent arterioles into larger cells which group around the glomerular vascular pole have been described (reviewed by Smith¹⁶). Although disagreement exists as to the character and normal distribution of these cells, they are regarded by some as of epithelioid nature and are stated to contain fuchsinophilic granules. Largely on the basis that these cells are hypertrophied and their granules more numerous in experimental and clinical states associated with hypertension,^{17, 18} it has been suggested that this "juxta-glomerular-myofibrillary organ" is the site of renin formation.¹⁹ Although the evidence which supports this view is entirely circumstantial, it is at least noteworthy that the position of these cells in the kidney is such that they are exposed to the extremes of pressure which occur in the afferent arterioles.

RENAL PRESSOR SYSTEM

It has been assumed in part of the above discussion that the liberation of renin somehow leads to the establishment of experimental and, possibly, of clinical hypertension. This association of renin to hypertension must now be examined.

The existence of renin, a proteinlike pressor substance in renal cortex, was first observed in 1898.²⁰ Various aspects of the original study have been confirmed and extended, largely as an aspect of the recent renewal of interest in renal hypertension. Methods of purification of renin have been described,²¹⁻²³ since crude extracts of kidney are contaminated by depressor substances.

It was observed that purer fractions of renin had little or no effect on the blood vessels of isolated organs (dog's tail, rabbit's ear) perfused with Ringer's solution,²⁴ while the addition of blood, plasma, or pseudoglobulins of plasma to renin in Ringer's solution resulted in prompt vasoconstriction. It was concluded that the pseudoglobulins of plasma contain a substance tentatively connoted renin activator. The activation of renin was then shown to be due to the interaction of renin and renin activator, with a resultant liberation of a third substance, angiotonin.²⁵ Angiotonin, unlike renin and renin activator, is not a protein. It is thermostable and dialyzable, and certain of its crystalline derivatives have been prepared. Its action as a pressor substance is both prompt and of short duration, and is, therefore, unlike the slower rise and sustained increase of arterial pressure which follow injections of renin.

Repeated injections of renin into normal animals result in a loss of pressor responsiveness (tachyphylaxis) which, in part, is due to a loss of activator by

combination with the injected renin. However, restoration of activator by transfusion or injection of activator concentrates does not fully restore the pressor action of renin. Repeated injection of angiotonin causes loss of responsiveness also, but this tachyphylaxis does not develop as rapidly as that due to injection of renin and plasma transfusion, and injection of activator does not affect it. Bilaterally nephrectomized animals are sensitized to the pressor action of renin and angiotonin and do not develop tachyphylaxis to angiotonin and only slowly to renin. Angiotonin tachyphylaxis and the residual inhibition of the pressor action of renin after restoration of activator, therefore, seemed to be due to the liberation of an angiotonin inhibitor from the kidneys.²⁸

Harrison, Grollman, and Williams,²⁷ and one of us and co-workers²⁸ have been successful in attempts to extract such an inhibitor or antipressor substance from the kidneys. The evidence at present available indicates that we are dealing with the same active principle as that reported shortly before by Harrison, Grollman, and Williams. Our work was based on different reasoning and was done independently. The two groups are now collaborating toward a further solution of the problem. The *in vitro* activity of such extracts on angiotonin (hypertensine) has recently been reported.²⁹

To summarize, the pressor system may be considered as originating in renin which, when released into the blood, combines with renin activator to yield angiotonin. Angiotonin acts as the effective vasoconstrictor and pressor agent. Opposing or balancing the action of angiotonin, the kidney contains a substance which acts as an inhibitor of the action of angiotonin. The relation of this pressor system to experimental and clinical hypertension is suggested by the following observations: (a) renin is present in the renal venous blood of hypertensive but not of normal animals; (b) the blood of hypertensive animals and human beings has properties which suggest that it contains less angiotonin inhibitor than normal blood; (c) nephrectomized and, possibly, hypertensive animals are more sensitive to the pressor action of angiotonin than are normal animals; (d) the peripheral blood of hypertensive animals and human beings contains a vasoconstrictor which, like angiotonin, is potentiated in the presence of blood from nephrectomized animals³⁰; (e) as will be discussed below, the nature of the pressor action of angiotonin is not inconsistent with that of a substance which might participate in the genesis of hypertension.

Independent and almost simultaneous confirmation of this concept of the humoral pressor system in hypertension is given by the findings of Braun-Menendez, Fasciolo, Leloir, Muñoz, Taquini, and Houssay, of Buenos Aires.³¹ These workers have also shown that a pressor substance, apparently renin, is liberated from ischemic kidneys and, proceeding from the observation that renin is not in itself vasoactive,^{24a} have shown that it interacts with a pseudoglobulin, renin activator (called by them hypertensinogen), with liberation of an effector substance, similar in physiologic properties to angiotonin, to which they refer as hypertensine. The chemical similarity or identity of angiotonin and hypertensine remains to be established. Indirect evidence has led them to the conclusion that there exists in normal kidneys an angiotonin inhibitor, called by them hypertensinase, since it is their view that it may act by enzymatic destruction of hypertensine (angiotonin).

Other pressor substances have been described as originating in the kidney. Thus, "perfusin" which, unlike renin and angiotonin, is potentiated by cocaine, has been obtained by perfusion of the kidneys of normal hogs and dogs with Ringer's solution.³² A substance, whose properties are not unlike those of renin, is found in the renal venous blood of *completely* ischemic kidneys and has been provisionally called ischemin.^{33a} It now appears that this substance is renin.^{33b} Also interesting in this connection is the observation that isolated ischemic kidneys or anaerobic kidney tissue *in vitro*,^{34a} as well as completely and partially ischemic kidneys *in vivo*,^{34b} form a pressor substance, apparently hydroxytyramine, from "dopa" (dihydroxyphenylalanine). This substance, like "perfusin," is potentiated by cocaine and may be similar to the pressor substance formed during the anaerobic incubation of kidney tissue.³⁵ These observations are of particular interest in view of the reported activity of tyrosinase in restoring to normal increased arterial pressure in hypertensive rats and dogs.³⁶ It should, however, be observed that formation of apparent hydroxytyramine is largely restricted to conditions of anaerobiosis and extreme oxygen want, whereas the oxygen content of renal venous blood in hypertensive dogs, even in the presence of moderate renal ischemia, is within normal limits.^{4, 11} It is doubtful whether anaerobic conditions could prevail in kidneys while the oxygen content of the blood remains unchanged.

RENAL FUNCTION IN HYPERTENSION

The supposed integrity of the kidney in hypertension was based largely on the absence of proteinuria and hyposthenuria and on the normal urea clearance of many hypertensives, since it was assumed that an abnormality of renal function would be revealed in one or the other of these tests. Unfortunately, hyposthenuria, when present in mild degree, may not manifest itself unless efforts are made to obtain urine of maximum specific gravity, as in the Addis concentration test, and, when such efforts are made, it can be shown that the majority of hypertensives whose urea clearance is normal show definite impairment of the maximum ability to concentrate urine (Chart 2). More recently developed methods of study of renal function have shown that even in early cases of hypertension there is evidence of some degree of renal ischemia, apparently due to constriction of the glomerular efferent arterioles. These methods, the determination of the clearances of diodrast, phenol red, and inulin, and of the maximum ability of the kidneys to secrete diodrast and reabsorb glucose, have been developed and widely applied by Smith, Shannon, Goldring, Chasis, Ranges, and their co-workers.^{16, 37}

Briefly, inulin is excreted only by glomerular filtration. Its clearance (volume of plasma equivalent to the amount of inulin which appears in the urine each minute) is, therefore, equal to the volume of glomerular filtrate formed each minute. Diodrast, on the other hand, is excreted largely by tubular secretion, i.e., by transfer of diodrast from the plasma of the peritubular capillaries across the cells of the proximal convoluted tubules into the tubule lumen. This removal of diodrast from blood in the kidney is nearly complete at low plasma concentrations of diodrast, i.e., when diodrast is excreted at less than a maximum rate. If renal diodrast load is large, so that more is present in the kidney than

can be transferred by its cells, the removal of diodrast from blood then becomes less complete, since excretion is already at a maximum. However, since at low diodrast loads extraction approaches completion (80 to 90 per cent), it follows that diodrast clearance at such loads is nearly equivalent to renal plasma flow, or, at least, to the rate of flow of plasma to functioning tubular areas (effective renal plasma flow). It may be assumed that the proportion of diodrast left in the renal blood at low renal loads (10 to 15 per cent of that present in arterial

Chart 2.—Relation of urea clearance and maximum urinary specific gravity in 72 cases of essential hypertension. Abscissa (urinary specific gravity by Addis test) and ordinate (urea clearance) are plotted logarithmically. Maximum urinary specific gravity is within normal limits in only 22 instances, while normal values of urea clearance were observed in 50 patients.

blood) represents that volume of total renal blood flow which traverses supporting and nonexcreting renal tissues. A small proportion of the urinary diodrast is obtained from the red blood cells, so that it is inaccurate to assume that urinary diodrast is wholly derived from plasma. For practical purposes, since the proportion of diodrast added from the red blood cells is equivalent only to from 10 to 15 per cent of the diodrast excreted, it may be assumed that apparent plasma diodrast clearance is nearly equivalent to total renal plasma flow.^{38, 39} It follows that renal blood flow may be calculated from plasma diodrast clearance if the fraction of plasma present in the blood (1-hematocrit index) is known. Normal levels of diodrast clearance, renal blood flow, inulin clearance, and ability to excrete diodrast in man have been established.⁴⁰

Phenol red is excreted by a mechanism similar to that of diodrast, but, apparently, less efficient, since only about 50 per cent of the phenol red is removed from the blood.⁴¹ Phenol red clearance is, therefore, equivalent to roughly 50

per cent of renal plasma flow, and, in man, to about 56 per cent of plasma diodrast clearance, viz., roughly 375 c.c. per minute per 1.73 square meters of body surface.

Simultaneous measurement of inulin and diodrast clearances yield values equivalent, respectively, to the rate of glomerular filtration, i.e., the volume of water removed from the plasma by filtration; and to the volume of plasma from which the filtrate was formed. Increased intraglomerular pressure increases the proportion of water squeezed from the plasma through the glomerular capillaries, and thus increases the ratio of $\frac{\text{inulin}}{\text{diodrast}}$ clearance (filtration fraction). This ratio, which represents the fraction of plasma water filtered, is, therefore, a measure of changes of intraglomerular pressure. In hypertension, diodrast clearance, i.e., renal plasma flow, is usually decreased below normal levels, while inulin clearance is maintained. The normal level of inulin clearance depends upon increased intraglomerular pressure. The increased intraglomerular pressure of hypertension is due neither to the high level of systemic arterial pressure nor to their dilatation of the afferent arteriole, since either of these changes would of themselves increase renal blood flow, which, in hypertension, is decreased. It follows that both the decreased renal plasma flow and the maintenance of filtration rate in hypertension are the result of constriction, predominantly of the glomerular efferent arterioles.⁴²

The increased filtration fraction of hypertensives maintains glomerular filtration within normal limits long after there has occurred a marked decrease in renal blood flow, and thus explains the maintenance of normal urea clearance until late in hypertension, since urea is also excreted by glomerular filtration. This fact also may explain the observation that concentrating power usually fails before urea clearance decreases, since the concentration of urine depends upon the capacity of the renal cells to work, and it may well be that the ischemic cells of hypertensives are unable to work efficiently. The maintenance of glomerular filtration also implies that recourse to measurement of the blood levels or clearances of the other substances excreted by filtration (nonprotein nitrogen : urea nitrogen ratio, suerose, creatinine, xylose clearances) will be of no more value than determination of urea clearance. The normal urea clearance in hypertension is not an expression of functional renal integrity, since it is usually associated with renal ischemia, but, on the contrary, is usually evidence of renal vasoconstriction, which may be intense. For example, an increase of filtration fraction from 0.20, a normal level, to 0.30, a value not infrequent in essential hypertension, is enough to maintain urea clearance at 100 per cent of normal at a time when renal blood flow has fallen from a normal level of 1,000 to an ischemic level of 600 c.c. per minute.

Technically, the measurement of the simultaneous clearances of diodrast and inulin is not difficult, although it is necessarily more painstaking than routine determination of urea clearances. It is our view that the advantages of these determinations outweigh the difficulties of technique. Briefly, diodrast and inulin in sterile 0.9 per cent sodium chloride solution are given by slow intravenous infusion after the more rapid injection of a concentrated priming dose of the mixture. When it is believed that the plasma levels of diodrast and

inulin have reached a satisfactory level, which will be maintained by the infusion, the patient is catheterized, the bladder is rinsed out with sterile saline, and the urine and washings are rejected. A sample of blood is then obtained, and the bladder is again washed and urine is collected in about twenty minutes. Urine and washings are combined, and the time washing is completed is noted as the end of the first clearance period. Subsequent periods are collected in the same manner, although, with a constant infusion, sampling of blood is necessary only in every other period. We have adopted the routine collection of three urine specimens and two blood samples, and find this satisfactory unless unusual difficulty is noted in the collection of urine, in which case further collections are made. The necessity of intravenous infusion may be avoided by subcutaneous injection of a concentrated solution of diodrast, inulin, and novocain,⁴³ and the subsequent determination of clearance is made during a fall in plasma concentrations of diodrast and inulin, so that blood samples should be obtained in each period. Clearance is calculated as UV/P , where U equals urine concentration in milligrams per 100 c.c. and V is the volume of mixed urine and washings in cubic centimeters per minute, while P is the mean plasma concentration during the clearance period expressed in milligrams per 100 c.c. The value of P is obtained by interpolation from observed values to a point in each period approximately one minute before the midpoint of each period, thus allowing a delay time of one minute for the passage of urine down the renal tubules and ureters. Methods of diodrast analysis have been described by Smith, Goldring, and Chasis,⁴⁴ and by White and Rolf.⁴⁵ Methods of inulin analysis in present use are those of Alving, Rubin, and Miller,⁴⁶ and of Corcoran and Page.⁴⁷ We are at present using a slight modification of the method of White and Rolf for diodrast analysis.

The simultaneous measurement of diodrast and inulin clearance may be extended to the measurement of the maximum capacity of the kidney to secrete diodrast. Whereas efforts are made in the determination of renal plasma flow to maintain renal diodrast load (renal plasma flow \times plasma diodrast concentration) at levels such that the capacity of the kidney to transfer diodrast is not taxed and the removal of diodrast from blood is thus kept at a maximum, the determination of maximum capacity to secrete diodrast demands that the diodrast load be sufficient, so that secretory capacity of the kidney is overtaxed. Under such conditions, the diodrast excreted by the kidney by secretion (diodrast present in urine—diodrast excreted by filtration) reaches a constant level, which is expressed in milligrams per minute. The value expresses the maximum capacity of the diodrast transfer mechanism and, since the mechanism of transfer depends upon activity of the tubule cells, it follows that the maximum diodrast secretion rate is an expression of the mass of functioning tubular tissue. This value has been denominated Tm_D (tubular mass, diodrast). Clearly, interpretation of the absolute levels of diodrast and inulin clearances with reference to Tm_D is a more accurate expression of the status of renal hemodynamics than is their reference to average normal values, since thus stated, the value $\frac{\text{diodrast clearance}}{Tm_D}$ is an expression of cubic centimeters of plasma flow per unit of tubular tissue. Errors of interpretation due to differences in kidney size

in people of similar surface area are, therefore, excluded. Hypertensives, whose diodrast clearance may be normal with reference to surface area, may by this means be shown to have a decreased blood flow in cubic centimeters per unit of tubular tissue,⁴² i.e., with reference to renal mass.

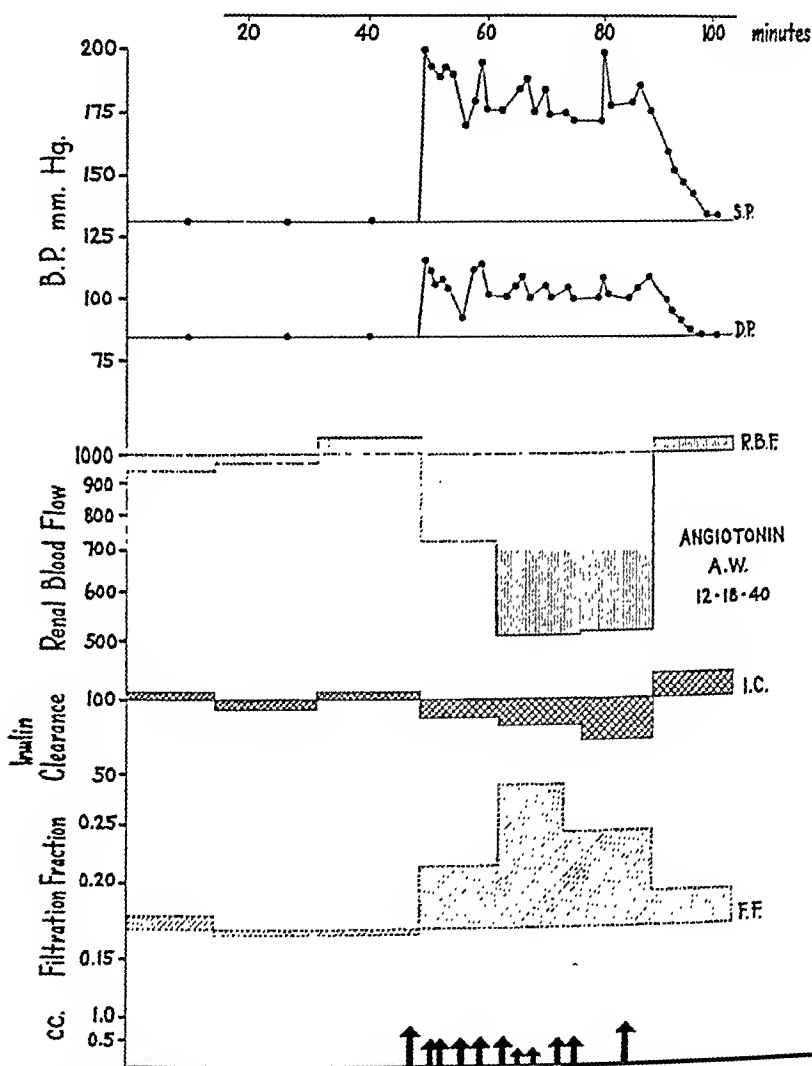

Chart 3.—Effects of infusion of angiotonin on arterial blood pressure, renal blood flow, inulin clearance, and filtration fraction in patient A. W. Ordinates from above downward: arterial systolic (S.P.) and diastolic (D.P.) blood pressure in mm. Hg.; renal blood flow (R.B.F.) in cubic centimeters per minute; inulin clearance (I.C.) in cubic centimeters per minute; filtration fraction (inulin/diodrast clearance ratio, F.F.); cubic centimeters of initial fluid. Effective intravenous injection of angiotonin and of subsequent renal blood flow, inulin clearance, and filtration fraction are plotted semilogarithmically. Abscissa: time in minutes.

Application of these methods to the study of renal function is shown in Charts 3 and 4. Chart 3, which illustrates the effect of angiotonin on renal circulation, also demonstrates the similarity of the functional change due to angiotonin to that which is present in hypertension. Injection of angiotonin in human beings increases arterial pressure and greatly decreases renal blood flow, but decreases only slightly the rate of glomerular filtration, because, as in hyper-

tension, there occurs increased extraction of water from the glomerular plasma (increased filtration fraction).⁴⁸ Angiotonin, therefore, constricts the glomerular arterioles. Its renal action is such that it may be the pressor substance of hypertension. In this connection, it should be noted that the renal ischemia

Malignant Hypertension: Effect of Renal Extracts

Chart 4.—Action of renal extracts on renal hemodynamics and arterial pressure in malignant hypertension. Numerals on abscissa refer to days in each series of intramuscular injections of renal extracts, while ordinates are referred to average normal values.

of hypertension, if due to angiotonin, is more probably a result of the action of the vasopressor system than a cause of the condition. A similar, apparently secondary, renal hemodynamic abnormality is present in the diastolic hypertension associated with coarctation of the aorta.⁴⁹ A further similarity of angiotonin to the possible pressor agent of hypertension, and one which excludes adrenin and pituitrin, is the fact that angiotonin exerts its pressor action without causing pallor or a decrease of skin temperature.⁵⁰ This is also true of renin.^{41, 51} Others have shown that the acute pressor action of angiotonin is associated with greatly increased peripheral resistance and with decreased

cardiac output⁵² and increased venous pressure,⁵³ the latter possibly the result of the heart's emptying against great resistance. Angiotonin also increases the force of the heartbeat⁵⁴ and cardiac work and efficiency, but it decreases diastolic cardiac volume.⁵⁵ It is interesting to speculate as to whether or not angiotonin would decrease cardiac output in the case of the hypertrophied heart of a long-standing hypertensive person.

Studies of normal renal hemodynamics by the clearances of diodrast and inulin have shown an apparent autonomy of renal circulation, which is largely exercised by variations in caliber of the efferent arterioles.⁵⁶ The normal tendency of the autonomous renal circulation is to respond to variations of systemic blood pressure and supply by changes of efferent arteriolar tone which maintain filtration rate near its normal level, at the same time varying the rate of renal blood flow. Since, as has been noted, renin may be liberated in response to pressure changes in the afferent arteriole, it is not illogical to assume that the renal vasopressor system may have a normal function in the autonomy of renal circulation, and hypertension may be an abnormal release of this mechanism. Teleologically, it is difficult to imagine a function of this system in the maintenance of normal arterial pressure, since the normal blood pressure level is not affected by bilateral nephrectomy.

Diodrast and inulin clearances have also been used in the study of the renal changes that result from the treatment of patients suffering from hypertension with renal extracts containing the renal antipressor, or with other agents. The decreased arterial pressure following sympathectomy in hypertension,^{57, 58} or the therapeutic use of thiocyanate,⁵⁹ is not usually associated with the undoing of the efferent arteriolar constriction, and it may be assumed from this that neither sympathectomy nor thiocyanate reverses the process that leads to increased arterial pressure and renal vasoconstriction.

The action of renal antipressor extracts, on the contrary, is associated with a concurrent decrease of arterial pressure and evidence of efferent arteriolar relaxation, an observation that adds to the evidence which suggests that these extracts in fact inhibit the action of angiotonin and the renal vasopressor system in hypertension⁶⁰ (Chart 4). The extent to which renal blood flow is affected by renal vasodilatation depends upon the balance between renal vasoconstriction, vasosclerosis, and arterial pressure, so that it is not greatly increased when renal vasodilatation is associated with decreased arterial pressure.

The measurement of diodrast, phenol red, and inulin clearances has also yielded interesting information as to the renal functional changes present in pre-eclamptic and eclamptic toxemia of pregnancy.⁶¹ The succession of these changes in two patients with eclampsia before and after delivery is shown in Chart 5. Briefly, pre-eclampsia and eclampsia were characterized by a decrease of filtration fraction, which seems to be an expression of swelling of the glomerular capillaries, since it is not usually associated with decreased renal blood flow. Other patients suffering from "toxemia of pregnancy" show an increased filtration fraction and a decreased renal blood flow. It is believed that in these latter the renal changes are an expression of a process identical with that of essential hypertension.

It will be noted that the afferent arteriole has been largely neglected in the foregoing discussion, in which emphasis is placed on constriction of efferent arteriole in hypertension. Structural, as opposed to functional, studies of the kidney in early hypertension have shown that the characteristic lesion is not situated in the efferent arteriole, but that it consists of hyalinization and sclerosis

Chart 5.—Renal hemodynamics and arterial pressure in "toxemia of pregnancy." The numerals on abscissa refer to the day of observation in number of days ante (A) or postpartum (P). These cases were referred to elsewhere⁶¹ as patients No. A1, A2, B4, and B3.

of the afferent arteriole. Afferent arteriolar sclerosis may, in fact, be widespread at a time when there is little evidence of abnormal arteriolosclerosis elsewhere in the body.⁶² A possible explanation of this curious opposition of structural and functional changes may be obtained from consideration of vasosclerosis as it occurs in experimental renal hypertension. In this condition, the kidney is exposed, as are other organs, to the vasoconstrictor, apparently angiotonin or a similar substance, which is present in systemic blood, while it is at the same time protected from the increase of arterial pressure by the restriction of a clamp on the renal artery or a scar around the parenchyma. The kidneys of such animals rarely show evidences of sclerosis or of arteriolonecrosis in malignant hypertension, although these changes are widespread in other organs⁵ and

may be present in the contralateral "normal kidney."⁶³ The vascular degenerative changes are, therefore, apparently due in part to the increase of systemic arterial pressure and not alone to the presence of vasoconstriction. It is, therefore, altogether fitting that sclerosis should occur in the afferent (high pressure) arteriole at a time when it is absent in the efferent (low pressure) arteriole of the kidney.

The early afferent arteriolar sclerosis of hypertension has at the same time a significance other than that of a simple result of the action of increased arterial pressure, for, if it were present from other causes *before* the onset of hypertension, it would act effectively as would "myriads of little clamps."⁶⁵ Evidence of such a change prior to the onset of hypertension is unavailable, although the wide distribution of renal sclerosis in early hypertension is at least suggestive.⁶²

The final origin of hypertension remains obscure, for the demonstration of the part played by the renal pressor system clarifies some aspects of its etiology but, at the same time, poses new problems.

Addendum: Recently published observations correlate the diastolic arterial pressure of patients with hypertension with the rates of renal blood flow and glomerular filtration (Friedman, M., Selzer, A., Rosenblum, H.: The Renal Blood Flow in Hypertension, *J. A. M. A.* 117: 92, 1941). A new method for the determination of diodrast has also been described (Alpert, L. K.: A Rapid Method for the Determination of Diodrast-Iodine in Blood and Urine, *Bull. Johns Hopkins Hosp.* 68: 522, 1941).

CLINICAL AND EXPERIMENTAL

CAPILLARY STUDIES IN RAYNAUD'S DISEASE¹

FELIX DEUTSCH, M.D., BOSTON, MASS.

WITH THE ASSISTANCE OF OTTO EHRENTREICH, M.D., AND OCTAVIA PIERSON, A.B.

INTRODUCTION

EXACT capillaroscopic investigations and functional tests in cases of Raynaud's disease in general, as well as in those studied before and after complete elimination of sympathetic innervation, promise to yield significant data as to the role of the autonomic influences on the capillary. The relationship to the neuroses which have found their symptomatic expression in this part of the circulatory system may also be elucidated.

This study is an investigation of the constitutional capillary disturbances, the functional processes in the capillaries and the capillary permeability in cases of Raynaud's disease. These factors were studied both before and after preganglionic sympathectomy.

It is impossible to discuss the work of the many outstanding investigators who have been interested in these problems from the physiologic and psychologic viewpoints.^{1-6, 11, 13-16, 19, 22, 23, 31, 33, 36} Raynaud himself suggested that emotional stress can precipitate an angiospastic attack.²⁹ In recent years the most extensive survey of the various concepts of Raynaud phenomena has been published by Hunt¹⁷ who states that in 50 per cent of the cases of Raynaud's disease the attacks are precipitated by emotional factors (surprise, fatigue, etc.). He denies, however, any relationship between this illness and the psychoneuroses. That psychic stimuli may cause attacks is a point also stressed by Simpson, Brown, and Adson,³⁰ and by White.³³ Recently, Mittelman and Wolff²⁵ discussed the interplay between affective and physical environmental influences in a case of Raynaud's disease in which they could show the significance of emotional factors in the precipitation of the attacks.

Mueller and Parisius²⁷ were among the first to call attention to the relations of capillary disorders to the neuroses. They found "imbalance, disharmony, and dysergia in the psychic as well as in the organic sphere" to be characteristic for the vasoneuroses in general. These features are manifested in the form and function of the capillaries. According to these authors, a very frequent characteristic of the vasoneuroses is the "spastic-atonie symptom complex," "vasoneurotic diathesis," that is, not only prolonged widening and narrowing of the capillary lumina, but also, either simultaneously or in quick alternation, dilata-

Received for publication, June 27, 1940.

tion and constriction. In all the more severe vasoneuroses the flow is extremely changeable and irregular. At times the stream flows quietly and evenly, then very quickly; at times it is sluggish and "granular," then it ceases completely for a brief interval. Often these various phenomena can be seen simultaneously in different capillary loops in the same microscopic field. Often a continuous capillary flow becomes granular. The "granular flow," in addition, may begin in the arterial as well as the venous limb. At times even spontaneous refluxes from the venous to the arterial limb are found, a phenomenon previously thought to be seen only in marked congestive failure.

In the majority of vasoneurotics Mueller and Parisius found an increased number of somewhat congested papillary capillaries and more vessels in the subpapillary plexus. (They examined the skin of the interclavicular groove.) In a small number of cases no abnormal overfilling of the vessels was seen; on the other hand, often no capillaries at all were visible. The size of the capillaries also deviates from the norm. Frequently there are long and thin loops, at times very short, thick, irregularly distributed loops. The most striking, and indeed the most pathognomonic, capillary form which is found in vasoneurotics is the irregular rete mirabile. At the nailfold the loops are not quite parallel; rather, they converge or diverge in an indefinite fashion. As a rule, the arterial limb is very narrow, the venous rather wide and irregular; a variable number of anastomoses connect the individual loops. Finally, the subpapillary plexus is usually visible and shows very wide vessels. Besides the characteristics mentioned above, according to Mueller and Parisius, there is also a functional disturbance in the permeability of the capillary walls which can be seen microscopically in the more severe forms of the vasoneuroses, is the hemorrhagic diapedesis, occurring either spontaneously or after slight mechanical trauma. The above capillary picture, as defined by Mueller and Parisius, was later confirmed by many other authors.

MATERIAL

From the capillaroscopic investigations of a series of cases presenting pathologic conditions, 42 patients, 29 of whom had Raynaud's disease, were selected for the purposes of this study. The other 13 patients were included either for purposes of comparison because of the similarity of the symptomatic picture, as, for example, Buerger's disease, or because, for one reason or another, a sympathectomy was performed and they, therefore, seemed to be of particular interest.

Forty-two hands of nonoperated patients were examined. Forty-six hands were of patients who had had a sympathectomy at the time of examination; 16 of these had also been seen before operation. Frequently the same patient was examined several times, particularly if an operation had been performed, in order to be able to observe the capillary changes at various times postoperatively.

METHOD

Before the capillaroscopic examination was performed, the following clinical data were obtained: The body habitus and its deviation from the standard types was noted. The color, pigmentation, approximate temperature, degree of moisture or dryness, fat content and separability of the skin from the subcutaneous

tissue were indicated. The skin was tested for dermatographism. The vasomotor instability was checked by the absolute pulse rate and by the respiratory arrhythmia during inspiration and inspiratory apnea (Valsalva test). The systolic and diastolic pressures and their response to pressure on the carotid sinus were recorded.

CAPILLAROSCOPY

A Zeiss capillaroscope with a 60 \times objective and a 10 \times eyepiece was used. Since the small lamp within the tube does not offer adequate elimination, a special lighting apparatus for this purpose was attached. A special attachment permitting simultaneous observation and photography was inserted.

The morphology of the capillaries was described, with particular reference to developmental disturbance (archicapillaries, subcapillary plexus).¹⁸ The corium was described as being well scalloped, not well scalloped or straight.

The number of capillaries per field in the first row was counted.

The length and width of the capillaries and changes in their appearance were noted.

The flow in the capillaries was described as granular or uniform, slow or fast, intermittent or continuous, and the appearance of "gaps" and periods of stasis were noted.

In addition, the following tests were done in order to gain better insight into the functional responses: The flow in the capillaries was studied after occluding the arterial and venous flow by the use of a blood pressure cuff quickly pumped up to 30 mm. above systolic blood pressure. The "reflux time,"³⁴ the eventual reversal in flow from the venous side to the arterial and any other changes appearing in this experiment were noted, with particular attention to the widening, narrowing, or disappearance of capillaries.

Finally, by slowly reducing the pressure in the sphygmomanometer cuff (about 10 mm. per 2 seconds), the height of the pressure at which the capillary flow reappeared was determined. This value we termed "critical capillary pressure."

A phenomenon to which special attention was paid was the occasional appearance of a light-refracting, collagenous tissue fluid which exuded from the large capillaries and obscured them. This was seen spontaneously as well as in the tests for reflux time. As will be explained later, this may be regarded as direct expression of increased capillary permeability.

With a special photographic apparatus, a series of colored films was taken which recorded the capillaries themselves in addition to the shading of the surrounding tissue. However, more distinct pictures were obtained by placing a green filter in front of the light, and the black and white photograph with panchromatic Agfa or Kodak film combined the advantage of a clear, sharp picture, with facility in making any desired enlargement.

When it was of no particular importance to record the width of the capillaries, but of more importance to obtain the general outline, a slight congestion of the capillaries, produced by the blood pressure cuff (50 to 60 mm.) was shown to be most advantageous in obtaining clear pictures. Of course, such photographs, taken in a congested state, cannot be used for the determination of the

actual width of the capillaries; on the other hand, if anastomoses to the vessels of the subpapillary plexus are visible microscopically, these become much clearer and are then more easily photographed.

An attempt on the part of different observers to draw the picture the same size as seen in the microscope will give varied results and will lead to pictures of very different dimensions. Keeping in mind Krogh's criticism¹⁰ of the existing capillary pictures in the literature and the lack of data on the degree of magnification, we used the following method in our study: We set up a counting chamber for red blood cells under the microscope and photographed it; thus we had a sharply delineated scale for all sharply focused capillaries. Our original photographs were thus magnified 18 \times .

By means of the picture of the counting chamber it was not difficult to prepare enlargements giving a definite magnification of the actual size of the object. We merely had to place a scale on the projection surface of the enlargement apparatus and arrange it in such a way that, for example, the intermediate space of the counting chamber which is $\frac{1}{20}$ mm. long, appeared exactly 2 cm. long, in order to obtain a 400 \times enlargement.

By this method errors in the determination of the size of the microscopic picture can be avoided. Brown⁵ made such errors; he later had to correct his measurements because of incorrect calculation of the scale. Similarly, the photographs of Duryee and Wright¹¹ are incorrectly computed. In their paper two photographs are reproduced with the statement that the enlargement is "176 times on the original film" and "the enlargements shown are about four times the size of the original film." That means then that the picture reproduced was enlarged 176×4 or 704 \times . In order to check their data we measured the largest capillary loop in their picture; it was 5 cm. long. In reality it would then be $50/704$, or 0.071 mm. long. This would be only 10 \times as large as the average red blood cell. There must, therefore, be a mistake in their calculation.

REFLUX TIME AND CRITICAL CAPILLARY PRESSURE

The method used is to encircle the upper arm with a blood pressure cuff which is quickly pumped up to 30 mm. above systolic blood pressure. The time required for the blood in the capillary under observation to stop flowing is the "reflux time," which under normal conditions averages fifteen seconds. Lange¹² found a lower value in normal persons. We must go well above systolic pressure to be sure the arterial flow is completely shut off. It is important to wait several minutes before the test is repeated, because this length of time is necessary before the venous congestion completely disappears.

When the compression is released, the capillary flow reappears in normal persons at a pressure between 10 and 25 mm. below the systolic blood pressure. This we have termed the "critical capillary pressure." A reappearance above or below these limits must be considered pathologic.

NORMAL CAPILLARY PICTURES IN ADULTS

By means of capillaroscopy one sees the following picture at the nailfold of normal adults: The boundary between the cutis and corium is well scalloped. The capillaries of the first row (*limbus capillaries*) are, for the most part, hair-

pin-like; some show loops or figure-of-eight forms. They are usually parallel. The arterial limb is narrower than the venous and allows blood corpuscles to pass through only one by one. According to Mueller,²⁰ the patent width of the lumen is 0.009 to 0.012 mm. The venous limb is wider and allows two or more blood cells in a row to pass through. The width of the lumen, according to Krogh,¹⁹ is 0.02 mm.

The height of the capillaries, that is, the straight line between the foot of the capillary, where it is just visible, to the convexity of the arteriovenous transitional loop is about 0.2 to 0.4 mm. The distance of the capillaries from one another is approximately uniform. The number of capillaries in the first row is about 7 to 10 per millimeter. The distance of the heads of the capillaries from the corium is about 0.1 to 0.3 mm. The connection between these capillaries and deeper vessels is normally not visible.

Behind the above-described row of capillaries, which is just adjacent to the corium, there is usually a second, and often a third, row of shorter, but otherwise similarly formed capillaries. In the deeper layers no arrangement in rows can be made out, but one sees rather chessboard-like patterns or scattered, short loops which represent the capillary heads.

Normally the subcapillary plexus is invisible.

The above-mentioned loops and figure-of-eight forms, if present in the minority, are considered normal; so, too, are slight deviations from the very regular structure, such as slight variations in the length of the capillaries or a slightly unequal spacing.

The flow in normal capillaries is usually smooth and even and of moderate speed, but a "granular" type of stream is sometimes seen and occasionally isolated capillaries seem to disappear. Actually this is due to the fact that they contain no blood corpuscles, since it is only these that are visible and not the capillary itself. At other times the circulation in isolated capillaries ceases entirely for a brief period of time. Both of these phenomena are to be considered normal.

CAPILLARY PICTURE IN RAYNAUD'S DISEASE

The appearance and behavior of the capillaries in Raynaud's disease depend on the severity of the disease and are different in the different color stages of the extremities. In order to have comparable observations one must always perform the examinations in a warm room at a standard temperature. In this warm room the capillaries observed at the nailfold of a patient showed the same picture, even on different days, as long as no operation was performed.

The typical picture in a severe case of Raynaud's disease (in a warm room) is the following: Most of the capillaries are enlarged. The presence of giant capillaries with a width of 5 to 8 red blood cell diameters or more is striking. The space between the two limbs of such a giant capillary is about 10 red blood cell diameters. Its shape may be ringlike or hairpin-like or irregular and tortuous. The flow in the capillaries is slow and sluggish, and often prolonged periods of stasis are observed. In some cases blood extravasates and thromboses are found. Very often there are very narrow, thin capillaries between the enlarged, giant ones.

In severe cases which are combined with sclerodermic changes, all the above-mentioned findings may be present, and in addition, the number of capillaries is smaller. The picture is very often hazy and the flow is barely visible; the stream, if visible, is very sluggish. In the reflected light the tissue has a brighter color than in other cases, probably due to the increased collagenous fibers. In addition, the excretory ducts of the sweat glands are often visibly enlarged and dilated, and the escape of drops of sweat may be seen. Since we observed this phenomenon in several cases, it may be evidence that there is a hyperfunction of the sympathicus in Raynaud's disease. This confirms Raynaud's original concept²⁹ that one of the mechanisms of the disease is an abnormal vasomotor tone. Lewis' opinion²³ is that in true Raynaud's disease there is a "local fault" and that the vasomotor tone is normal. Bishop, Heinbecker, and O'Leary² believe in a local, inherent, trophic, etiologic factor. In some advanced cases a sensitization to humoral substances is present and is sufficient to produce an attack.

In early and mild cases of Raynaud's disease the picture is not so striking; giant capillaries, thromboses, and blood extravasates are absent. The typical picture in mild cases of Raynaud's disease or vasoneurosis is as follows: very tortuous, twisted and bent capillaries, usually with a spastic, narrow, arterial portion and a dilated, congested, venous portion. A congested subpapillary plexus is usually visible.

REFLUX TIME

In severe cases of Raynaud's disease the reflux time shows a marked deviation from the norm. We frequently find capillaries in which, upon compression of the arteries of the arm, there is an immediate stasis (the decision as to whether it happened *post hoc* or *propter hoc* is sometimes difficult, since spontaneous stases often occur). In the enlarged, giant capillaries, in which the flow before compression was very slow and sluggish, and in which there were frequent, spontaneous stases, we often observe that after compression this flow remains visible for a long time before it finally stops. Time intervals of more than one minute are not rare. (The experiment should not be repeated immediately; one must wait several minutes, otherwise the results will be incorrect.) As is to be seen from these contradictory findings under the seemingly identical conditions, we are concerned with a complicated function which apparently represents the resultants of various factors influencing the reflux time. This will be discussed later.

CRITICAL CAPILLARY PRESSURE

Observations of the reappearance of the capillary flow after compression show varying results in different cases. In several examinations of the same case at different times there is, for the most part, a rather constant pressure at which the flow reappears. The experiments must not be done immediately after one another; a rest of several minutes must be interposed. Those patients in whom the pressure at which the flow reappears varies on different examinations seem to belong to that group in which the blood pressure also changes frequently. In general, the capillary flow reappears normally at a pressure of about 10 to 25 mm. below the systolic blood pressure. A striking and abnormal finding was

Difference Between Systolic Pressure and Critical Capillary Pressure

obtained in severe cases of Raynaud's disease and scleroderma in that the pressure often had to be reduced 60 mm. below the systolic pressure before the capillary flow reappeared. Reappearance of the flow at a point 35 mm. or more below the systolic pressure seems to be due to a local disturbance in capillary function.

In Charts 1 and 2 this relationship is graphically presented. In Chart 1 the difference between systolic and critical capillary pressure is shown in comparison with the severity of the illness; in Chart 2 the differences before and after operation may be seen.

CAPILLARY PERMEABILITY

As mentioned above, in severe cases one frequently may see blood extravasations. This is to be regarded as a sign of increased capillary permeability. Moreover, in a few cases with giant capillaries, we were able to observe the following phenomenon: After the blood pressure cuff was pumped up, a light-refracting substance gradually began to cover these giant capillaries, and the entire field became hazy. This may have been due to a filtration of plasma through the capillary wall because of increased capillary permeability. The criticism that this phenomenon may be explained by a difference in the refraction of light by the giant capillaries lying beneath can be refuted by the fact that we had the opportunity to observe the appearance of this "shiny substance" after prolonged compression in cases in which it was not formerly present. It is, therefore, due to the passage of plasma substance through the capillary wall. In a subsequent examination at another time the capillary picture was again distinct. This may be considered as further proof in favor of our interpretation.

Patients whose fingers were edematous usually showed a vague, hazy, capillary picture. More often it was seen that the originally clear capillary picture became vague and hazy upon prolonged compression, indicating increased permeability. Capillary permeability and its correlation to adrenergic and cholinergic reactions was investigated by the autonomic skin test.¹⁰

CLINICAL AND CAPILLARY GROUPING

In Table I the results of the capillaroscopic examination are compared with the classification of the cases from the clinical and surgical viewpoints. The characteristics which are significant and particularly suitable for a tabular survey are as follows:

1. The presence of giant capillaries (noted in the table by +).
2. Sluggishness of flow (noted in the table by +).
3. The reflux time and the critical capillary pressure (see Method). If the difference between the systolic blood pressure and the critical capillary pressure is above 30 mm., this is noted in the table by +; a - denotes that the difference is less, and a dot that the experiment was not done.

The clinical grouping, from the surgical viewpoint, is as follows:

1. Group 1 of Raynaud (R_1): no obvious local changes on ordinary examination of the affected extremity.
2. Group 2 of Raynaud (R_2): obvious local changes.
3. Group 3 of Raynaud (R_3): obvious local changes and x-ray abnormalities such as bone atrophies.
4. Causalgia (C): pain a prominent symptom with secondary vasomotor changes.

In Table I we see that the plus signs tend to form a group which includes those patients who were also designated as group R_2 or R_3 clinically, whereas the groupings R_1 (mild cases) and C (so-called cases of causalgia) were frequently characterized in the table by minus signs. Insofar as we examined these patients preoperatively, these findings are noted in the table by minus signs. Those patients who were seen only after operation are noted in the table by plus signs. It may be concluded from experience with cases seen before and after operation that the above cases may also have had a pathologic picture before operation, i.e., giant capillaries and sluggish flow.

A comparison of the capillaroscopic and clinical groupings of Raynaud cases revealed certain discrepancies. For example, the nailfolds of Lop and Wic (Table I) showed less marked findings capillaroscopically than we would expect on the bases of the clinical classification, whereas Dwy and Goo showed more severe capillaroscopic findings. The past history of Lop reveals, however, that the signs and symptoms of the disease were localized only in the feet, never in the hands which were always free. She was placed in group 2 only on the basis of the findings in her legs, not in her hands. The patient actually had had only a lumbar sympathectomy. The seeming inconsistency in the classification is thereby explained.

As mentioned above, the capillaroscopic findings in patient Wic were those of a benign case, whereas the clinical impression was that of a moderately severe case. This case is here described in greater detail because of its other interesting features.

CASE REPORTS

CASE 1.—The patient was a young woman, aged 26 years, who impressed the physicians by her persistent complaints of pain in the hands and occasional blanching of the fingers. This was the reason for placing her in group 2, although according to the capillaroscopic exam-

ination she belonged in group 1. Psychologically, she had the personal characteristics of an obsessional neurotic. She showed interesting changes in the capillary picture upon repeated examinations at different times.

She was examined for the first time four months after a left-sided preganglionic sympathectomy. The left hand was dry and warm, the right hand moist, cool, and purple. Only the right hand was examined capillaroscopically at that time. There were signs of a developmental disturbance of the capillaries (expressed in the persistence of the subpapillary plexus and in visible anastomoses with the papillary capillaries) and a flow of moderate speed, a condition usually not found in moderately severe cases of Raynaud's disease.

When the patient was examined eight months after operation on the left hand and four months after operation on the right hand, she was still under the influence of a recent gynergen injection. She said that she was in the habit of taking these injections originally because of asphyxia of the finger, but now because of migraine; she claimed that these injections helped her. Her hands were cold, dry, and showed purplish spots when she entered the room. The most striking capillaroscopic finding was a very marked sluggishness of flow; often there was a complete lack of motion in the microscopic field.

Without being asked, but quite spontaneously, the patient gave the following information: Before the sympathectomy, whenever she had a gynergen injection, the hands became reddish, warm, and moist; since the operation, after a gynergen injection, her hands always became cold and purplish.

One month later the patient was again examined; she had had no gynergen injections for several days. The hands were reddish pale; the palms were colored bright red and were dry and warm. Capillaroscopically there was a rapid blood flow in the capillaries. In contrast to the former findings, the stream never became sluggish and no periods of stasis appeared. The capillaries which, preoperatively as well as at the time of the first postoperative examination, without being under gynergen influence, were found to be dilated, now had a normal lumen. Thus these findings show that the gynergen injection before and after operation had a different effect on the appearance of the hands and of the capillaries.

The influence of gynergen on the asphyxia of the fingers before operation is comprehensible, because ergotamine paralyzes the sympathicus and, therefore, in cases of Raynaud's disease with spastic, constricted arterioles, there is dilatation of the arterioles and thereby a better blood supply to the hands. As a consequence of this the hands become warmer and redder. After sympathectomy the sympathetic action on the arterioles is absent, and the gynergen action has lost its pathway. Nevertheless, as the capillaroscopic examination reveals, it must still have an effect on the capillaries.

According to Cannon⁶ and to our own findings, the sympathectomized zones are hypersensitive to adrenalin. Narrowing of the capillaries, which we found in most cases after sympathectomy, could be explained on this basis. There also seems to be an increased sensitivity to adrenalin-inhibiting substances, such as shown by the gynergen effect postoperatively. Capillaroscopic examination shows that after gynergen injection there is a dilatation of the capillaries in the sympathectomized region. Since this occurs without sympathetic regulation of the width of the arterioles, the consequence of the sudden, marked dilatation of the vessels is a slowing of the flow to the point of stasis. The cyanotic, blue-red color of the hands and the cool temperature are a result of this widening of the capillaries and the slowing of the flow.

The correctness of this assumption is confirmed by the third examination of the patient at a time when she had not received a gynergen injection. The findings were the same as in other sympathectomized patients: narrow capillaries, marked rapidity of flow, and warmth of the hands.

To summarize, the functional tests of the capillaries in the compression test in this patient may be discussed. Before operation on the right side (the left dorsal sympathectomy had been performed four months earlier) the reflux time was seventy-three seconds and the critical capillary pressure was 60 mm., that is,

55 mm. below systolic pressure (115 mm.). On examination of the right side four months after operation and while under the influence of ergotamine tartrate (gynergen), the reflux time in the right hand was thirty-five seconds and the critical capillary pressure was 80 mm., that is, 20 mm. below the systolic pressure of 100 mm. In the left arm, on which an operation was performed eight months previously, the reflux time was forty seconds and the critical capillary pressure was 84 mm., or 16 mm. below the systolic pressure.

One month later, without the influence of gynergen, the reflux time was twenty-five seconds on the right side and the critical capillary pressure was 90 mm., or 28 mm. below the systolic pressure (118 mm.).

Thus we see that the pathologic increase of the reflux time present before operation is significant, that postoperatively, with the patient under the influence of gynergen, it is less noticeable, and that without gynergen the reflux time is almost normal.

The variations in the critical pressure correspond to those in the reflux time. The pathologically low critical capillary pressure becomes distinctly higher after operation and, postoperatively, under the influence of gynergen, it is not so high as without gynergen. But since the blood pressure after the gynergen injection was only 100 mm., the difference between the systolic pressure and the critical capillary pressure ($100 - 80 = 20$ mm.) seemed somewhat less after the gynergen injection than later without gynergen ($118 - 90 = 28$ mm.).

CASE 2.—In the case of Goo there is also a discrepancy between the clinical picture and the capillaroscopic findings in the left hand. Clinically she was placed in group R₁, whereas the capillaroscopic findings were those of a more severe case.

She was a 33-year-old white, single woman, of slender build. Her skin was pale, her hands were cool and pinkish. On October 6, 1939, the date of examination, her pulse rate was 78 without any respiratory arrhythmia. Her blood pressure was 108/72.

Capillaroscopic examination of the right hand revealed a straight corium. There were 8 capillaries per field in the first row, irregular in form, most of them hairpin-like, but short, and some were half figure-of-eight shaped and widened. The width of the vessels changed during examination, some disappearing entirely. There was no marked difference between the arterial and venous limbs of the capillaries. The stream is slow and granular, and in some capillaries is invisible.

The second row reveals some hairpin-like, short, very widened capillaries. Others are dendritic and pointed. The subpapillary plexus is not visible.

Functional test: The blood stream stops after twenty-eight seconds, at a pressure of 130 mm. Hg., and starts again at 70 to 80 mm. Hg.

Capillaroscopic examination of the left hand reveals a straight corium. In the first row there are 6 widened, parallel capillaries, some hairpin-like, some twisted and dendritic. The venous limb is slightly wider than the arterial. The stream is sluggish and granular. In the second row the capillaries are diffusely located, some running horizontally. Some are very widened, sacklike shaped; some are short, some have biscuit forms. The subpapillary plexus is not visible; no archicapillaries can be seen.

Functional test: The stream stops at a pressure of 130 mm. after eight seconds and starts again at 65 mm. In a second test it stops after thirty-five seconds and starts again at a pressure of 55 mm. No retrograde flow is seen during compression.

Summary.—Irregularities in the form and location of the vessels. There are no developmental abnormalities of the capillaries, though there are obviously pathologic processes which lead to regenerative and degenerative changes. There are striking changes of the speed of the blood stream.

The subjective complaints of this patient contrasted strikingly with the objective findings in her hands, although she constantly reiterated that she had pain in her hands and legs. She was a severe obsessional neurotic whose interests were centered on sensations in her hands and legs. She insisted on procedures which gave her only transient relief. This explains the great number of operations which she underwent. They were as follows: at the age of 17, appendectomy; at 20, right ovarian cyst removed; at 31, left lumbar sympathectomy; at 32, in February, 1937, right lumbar sympathectomy; November 5, 1937, left dorsal preganglionic sympathectomy; November 13, 1937, right dorsal sympathectomy; December 16, 1937, left splanchnic resection; December 28, 1937, right splanchnic resection. On October 15, 1938, the patient had a right dorsal sympathectomy, and on November 14, 1938, resection of the fifth to the ninth left intercostal nerves. In spite of all these operations her neurotic complaints continued.

CASE 3.—Another case in which the clinical picture and capillary findings are not in agreement is the patient Dwy. The following are the salient features in this case:

Two and one-half years ago, in October, 1934, the patient crushed his left forefinger tip between two stones. He was seen immediately by his physician and after an x-ray had been taken, was treated conservatively at the local hospital. Later he was x-rayed again by an insurance company. The finger tip had become so sensitive, however, that he was unable to work because of his fear to touch anything with this hand. Two and one-quarter years ago the finger tip was amputated, but the extreme sensitivity remained. Whenever he touched anything, excruciating pain shot up the forearm. His sensitivity contrasted with the objective findings. Two years ago the pain sensation led to the diagnosis of neuroma, and the finger was amputated at the distal interphalangeal joint. No relief was obtained. One and one-half years ago another operation was performed, this time to remove the nerves on either side of the finger. The symptoms remained unchanged in spite of physiotherapy (massage, heat), and the finger seemed to be withering. Nine months ago another amputation was done, this time at the proximal interphalangeal joint, with no change in symptoms. A general physical examination at this time threw no light on the problem, and six "glass boot" treatments produced no change in the symptoms.

The patient has never before noticed numbness or tingling in the extremities or unusual sensitivity to cold. The sensitivity to touch and, more recently, extreme sensitivity to cold is now present in the whole left hand. On exposure to cold air the left hand turns numb and blue and requires ten to fifteen minutes to "thaw out."

On June 16, 1937, a left-sided sympathectomy was performed, with subsequent subjective improvement. The patient was examined for the first time eleven months later. Capillaroscopy at that time revealed in both hands a picture characteristic of a severe case of Raynaud's disease. On re-examination one year later (June 26, 1939) the changes were still more marked in the nonoperated hand. Even at the time of the first examination a large number of giant capillaries with a sluggish flow were found. Other capillaries showed a constantly changing rate of flow in that at times it was rapid and at times sluggish; occasionally it even stopped entirely for prolonged intervals. In addition, complete disappearance and reappearance of the capillaries was often observed. One year ago, in the right, nonoperated arm, the critical capillary pressure was 90 mm., that is, 30 mm. below the systolic blood pressure which was 120 mm. at that time, as it is now. In a follow-up examination on June, 1939, the critical capillary pressure was 60 mm.

From these findings we are justified in concluding that this patient must have had an asymptomatic Raynaud's disease at the time of his original injury. Afterward the accident precipitated a neurosis which revealed itself in his severe sensitivity and in the complicated postoperative course.

These examples show that severe capillary changes may be present in cases without or with inadequate clinical findings. In some cases neurotic complaints are in the foreground and antedate the visible clinical symptoms, since the basic capillary changes are not discovered.

CAPILLAROSCOPY BEFORE AND AFTER SYMPATHECTOMY

Before conclusions concerning the effect of the sympathicus on the capillary flow in Raynaud's disease are drawn from the comparison of capillaroscopic findings before and after preganglionic sympathectomy, the operation, as performed by Smithwick,³¹ is described: "A vertical paravertebral incision centered over the third rib is made. Inner inch of third rib is resected. Second and third intercostal nerves are identified. Inner inch is resected, dividing both anterior and posterior roots, as well as the rami to the sympathetic trunk. The sympathetic nerve is identified and resected below the third ganglion, and the upper end of the section fold is sutured to the insertion of the muscles of the back. The incision is closed with fine silk."

The clinical results of the preganglionic dorsal sympathectomy are as follows: Whereas, before the operation, the affected hand is usually purple and mottled, cold and moist, after the operation it is pale, warm, and dry. It is worthwhile commenting that to the unbiased observer the hand on the sympathectomized side becomes not redder, but paler; and, as mentioned, it is much warmer than before the operation. The difference can be seen most clearly in those patients who have been operated on one side only.

The comparison of the capillaries at the nailfold before and after operation shows changes in the following: (1) the width of the capillaries, (2) the speed of the capillary blood stream, (3) thromboses and blood extravasates, (4) the reflux time, (5) the critical capillary pressure, and (6) the number of visible capillaries.

After sympathectomy in cases of Raynaud's disease a distinct *change in width* of the capillaries could be observed. In the mild cases the abnormal width of the capillaries was decreased. Of the two most severe cases with giant capillaries, in one the capillaries narrowed conspicuously, in the other they did not change; of 6 cases with widened capillaries, 5 showed narrowing after operation (Chart 3). Of the whole group of 15 operated cases, 9 showed narrowing after operation.

The most striking change after operation is, however, the increased *speed of the blood flow in the capillaries*. Of the 11 cases examined for speed of flow before and after operation, 2 showed no change and 9 showed a more rapid flow (Chart 4). In 3 others, examined only after operation, but where comparison could be made with the unoperated hand, all 3 operated cases showed increased flow. The changes are best seen in the mild and moderately severe cases. In the most advanced cases also, even after operation, a sluggish flow is still present in the markedly dilated capillaries, but one sees clearly the tendency to increased speed of the blood flow in the relative rarity and brevity of the periods of stasis as compared to the behavior before operation.

In two cases (Lam, Syp) on re-examination a few weeks after operation, *thromboses and hemorrhagic exudates* could no longer be found, although these were seen before operation.

In one case (Pic) where the increased capillary permeability before operation was characterized by the light-refracting substance in the neighborhood of the giant capillaries, such a "shiny" substance was not present after operation

Chart 4.

and did not appear until after prolonged compression. This suggests a decrease in capillary permeability.

In the same patient it was also noted that the capillaroscopic picture, which had been very hazy before operation, became much clearer postoperatively. This was in obvious connection with the visible decrease in the swelling of the finger, i.e., with the decrease in the free fluid in the tissue. In addition, the dilatation of the excretory ducts of the sweat glands, which was present preoperatively, was no longer seen.

Capillaroscopic observations of sympathectomized Raynaud's disease have been published by Adson and Brown.¹ The authors discuss a case of Raynaud's disease which had a "resection of the sympathico-cervico-thoracic and second thoracic ganglion and the intervening trunk" on one side. They described the improved capillary flow, the brighter color of blood, and the narrowness of the capillaries on the operated side. The latter they attribute to increased tonus of the capillaries.

Change in the reflux time after operation varies, depending on its preoperative value and on the time which has elapsed since operation. In the group with decreased reflux time were cases with stases occurring after a few seconds as well as those with instantaneous stases. It was shown that the reflux time in these cases increases after operation. For example, in one patient (Syp), the reflux time before operation was only six seconds. On examination two weeks after operation the reflux time was seventy seconds, three weeks after operation, fifty-five seconds, and five weeks after operation, twenty-five seconds. After six weeks there was again a decrease in the reflux time, so that immediately after pumping up the blood pressure cuff there was a stasis in the capillary stream. Three months after operation the reflux time reached forty-five seconds, and six months afterward it was about the same, thirty-nine seconds.

In another patient (Whi) who showed a short reflux time of five seconds preoperatively, the same value was obtained on the fourth day after operation. On the fifth day the reflux time was 52 seconds, on the twelfth, fifteen seconds. However, this was observed three days after an operation on the other arm and the reflux time was fifteen seconds in both extremities.

In patient Che, who showed an immediate stasis upon compression before operation, the reflux time was eight seconds eleven days after operation.

In another patient (Lan), with a decreased reflux time on the right side to four seconds and on the left to five seconds, examination of the left hand five days after operation showed a reflux time of nine seconds, and sixteen days after operation, examination of the right hand showed a value of fifteen seconds.

Finally, in patient Lab, in whom, before operation, there was an immediate stasis of the capillary flow upon pumping up the cuff, the reflux time in the right arm was thirty-seven seconds one week after operation and eighteen seconds in the left arm two weeks after operation.

In some cases with a low reflux time no changes therein appeared during the first four days postoperatively, but the increase is first seen shortly thereafter.

This condition is particularly noteworthy because between the fourth and fifth days there is frequently also an unusual change in the appearance of the hand. Usually, during the first four days after operation, as Smithwick²¹ has often emphasized, the hand is still cold and moist, while on the fifth day it becomes warm and dry.

The curve for the reflux time in the above-mentioned case (Syp), as in other cases, shows that the increase in time which appears a few days after operation gradually decreases in the course of the following few weeks, but that later a value is established which does not change in the following few months and seemingly may be regarded as constant.

The values of the reflux time obtained for patient Whi create the impression that the operation on one side influences the postoperative results on the other side, since the reflux time in one arm, increased because of the operation, decreases at the moment a sympathectomy is performed on the other side.

In summary, it may be said that in cases of Raynaud's disease with lowered reflux time there is an increase after operation.

In discussing those cases with an increased reflux time before operation, it must be stated that in the majority they are severe cases. Here we see the opposite of what we saw in cases with decreased reflux time. After operation there is a significant decrease in reflux time, the value sometimes sinking below normal. Patient Pic, who was examined several times before operation, showed a markedly increased reflux time in her enormously dilated capillaries. However, it was striking that before operation a stasis could occasionally be seen immediately following compression. This, however, was not always due to compression, but was one of the frequent spontaneous stases which were characteristic of this case. These spontaneous stases ceased after operation. Sixteen days after operation the reflux time was fifteen seconds. Two and one-half months after operation the afterflow time in the right arm was twenty-six seconds, in the left, three months after operation, it was five seconds.

Another patient (Hor) who, before operation, had a reflux time of ninety seconds in the right hand and of sixty-five seconds in the left hand, showed a reflux time of eight seconds on the left hand fifty-one hours after operation on this side, and of five seconds on the fourth day after operation. On examination two weeks after left-sided preganglionic dorsal sympathectomy and one week after right-sided preganglionic dorsal sympathectomy, the reflux time in the right hand was twenty-five seconds.

In patient Pro, who, according to the clinical picture and the capillaro-scopic findings is one of the severe cases of Raynaud's disease, a reflux time of thirty-seven seconds was found before operation. Three days after left-sided preganglionic dorsal sympathectomy and twelve days after right-sided preganglionic dorsal sympathectomy the reflux time was thirty seconds on the left and thirty-five seconds on the right. Four days later, in the left hand, the reflux time was twelve seconds; in the right hand varying results were obtained in variously formed capillaries of different widths. In a narrow capillary a time of twelve seconds was found and in a widened giant capillary, thirty-two seconds, while in the deeper layers values of five seconds and eight seconds were obtained.

In general, it may be said that in cases with a pathologically increased reflux time, a sudden and excessive fall thereof occurs immediately after operation. Then its value gradually approaches a normal level.

In some patients with preoperatively prolonged reflux time in whom three or more months have passed since operation, findings of thirty-five to forty-five seconds reflux time have often been obtained, i.e., a moderately prolonged reflux time. This finding was obtained in 13 of 25 hands which have been examined to date. In few patients in whom there was no retrograde flow in the compression experiment, a reversal in the direction of flow was seen upon compression after operation.

The *critical capillary pressure* has a distinct relation to the systolic blood pressure. If the blood pressure cuff is pumped over the systolic pressure and kept at this level, no blood can flow through the arterioles and reappearance of the capillary flow is impossible. Those few cases which, paradoxically, have a critical capillary pressure above the initial systolic pressure can doubtlessly be explained by the fact that they have a markedly fluctuating blood pressure which rose above its initial value during the examination.

If we compare the preoperative and postoperative differences between systolic pressure and the critical capillary pressure, we almost always see that after operation the critical capillary pressure is nearer the systolic pressure than before operation. Of the 11 cases in which this observation was made before and after operation, 10 showed a decrease and one showed an increase (Chart 2).

An interesting phenomenon which we observed in several cases and which was clearly changed after operation is the following: A series of patients who bore the occlusion of the circulation in the compression experiment 1' - 3' without any symptoms, upon gradual release of the pressure, felt a distinctly painful sensation at about the level at which the stream reappeared capillaroscopically. After sympathectomy this pain was no longer elicited.

The number of capillaries per microscopic field visible at the nailfold before and after operation shows no marked variation. Our observations showed no increased number of capillaries such as described by others. In a few cases after operation the first row of visible capillaries was much further from the corium than before operation. This can be explained by the fact that the capillaries of the first row are completely emptied after operation.

Before these findings can be discussed, the correlations between the speed of the capillary flow and the pulse rate should be considered. Such a comparison in our patients shows that there is no direct correlation, but, on the other hand, in cases with slow pulse rates, both rapid and slow rates of flow are found. This did not surprise us, since in patients who had a unilateral sympathectomy we found a sluggish capillary flow contralaterally and a more rapid flow homolaterally. In nonoperated persons with Raynaud's disease who had a rapid pulse rate, we almost always found a sluggish flow on the affected side. Those patients whom we observed with pulse rates over 100 were severe cases of the disease.

This phenomenon might be explained by supposing that the high pulse rate represents a compensatory mechanism to bring about a better flow. One might also bear in mind that, according to various authors, in cases of Raynaud's disease there is an increased activity of the adrenals, and this in turn causes the higher pulse rate. In any case, it shows that capillary circulation is, to a great extent, independent of the main circulation and probably reacts to processes in the tissue.

A simple relationship between systolic pressure and the rate of capillary flow does not exist, since we find rapid as well as sluggish flow in cases with normal pressure. This is apparent in those patients operated on on one side only, since they show a rapid flow on the operated side and a sluggish flow on the nonoperated side.

In the nonoperated patients it was striking that in the group of those with particularly low blood pressure (80 to 110 mm.) the capillary flow was slow in 7 of 9 cases in the group.

DISCUSSION

We can now explain the previously mentioned postoperative pallor and higher temperature of the hand. The former is due to the narrowness of the capillaries which is now present. The latter is due to the increased rate of flow following the operation. One might say, rather, that the temperature of the hand is dependent on the amount of blood flowing through the skin capillaries per unit time, and this is partly dependent on the width of the arteries.

One must not assume therefore, that the acceleration of the flow seen microscopically is a consequence of the small diameter of the capillaries, but, because of the warmth of the hand, one must maintain that despite the narrowness of the capillaries the amount of blood flowing through them at a given time is greater after sympathectomy than before it.

The pallor of the hand observed postoperatively agrees with the findings of Dale and Richards,⁹ who made their observations on the unpigmented cat's paw and saw that the denervated extremity was distinctly warm, but at the same time paler than the pads of the normal foot.

The narrowing of the capillaries after sympathectomy occurs for various reasons. In describing capillary behavior we have avoided the use of the words "spastic" and "atonic" and have restricted ourselves to the words "narrowed" and "widened," in order to emphasize that the change in the width of the capillaries is not indicative of an active movement of the vessels. There is no doubt that the change in the width of the capillaries is not dependent to any great extent on the flow in the arterioles, but is for the most part the result of metabolic changes in the surrounding tissues. Dilatation of the arterial limb is due to a passive distention as a reaction to the environment and swelling of Rouget's cells, whereas narrowing is attributed to inhibition of the surrounding tissue which then compresses the capillaries. Dilatation of the venous limb is more the result of changes in the environment, i.e., of the production of acid metabolites. Since the capillaries have only endothelial layers, no smooth muscle and no connective tissue, the sympathectomy can affect only the arterioles. For this reason, the operation may help in part indirectly: (1) by elimination of the spasm of the arterioles bringing about an acceleration of the blood flow

and a consequent improvement in the local tissue metabolism; (2) through the liberation of a chemical substance (H-substance), the intermediary production of which was inhibited before the nerve fibers were dissected.

The improvement in the capillary condition and the narrowing, therefore, occurs because (a) after the elimination of the spasm the vis a tergo causes an increased rate of flow, (b) the content of the capillaries becomes more mobile, (c) the external pressure decreases due to the changed condition of the tissue, (d) the capillary wall becomes less permeable to the plasma, the blood becomes more dilute, the blood corpuscles less englobated. Each of these factors plays a role.

In consideration of the above-mentioned factors, the postoperative change in the reflux time becomes significant as a functional test. In the cases with sluggish blood flow and very short reflux time, the operation produced an increase in the reflux time because of the reasons discussed, an acceleration of the blood flow, diminution of the tissue pressure, and dilution of the blood. In the few cases with a sluggish flow and a reflux time lengthened because of the tremendous expansion of the capillaries, the operation provoked a relative reduction of the reflux time, particularly by relaxing the arterial spasm and improving the blood flow.

The critical capillary pressure depends on the same factors which affect the reflux time. As a result of the sympathectomy, the critical capillary pressure is nearer the systolic blood pressure, varying directly with the effect of the operation on the basic pathologic factors. The more rapid the capillary flow and the narrower the capillaries, the closer to systolic pressure is the critical capillary pressure.

All these observations show the manifold pathways by which the damaging factors lead to the development of Raynaud's disease. Emotional factors may play a role in the precipitation and in the continuation of these processes, but further study is needed before the importance of this role can be evaluated.

SUMMARY

In this investigation the capillary response was studied in 29 cases of Raynaud's disease.

1. Capillaroscopic observation of cases of Raynaud's disease shows that the disease may be present before the appearance of the clinical symptoms. In these cases abnormal capillaries can be seen when other vasomotor symptoms are not present.

2. In the majority of cases of Raynaud's disease there exists a persistence of the subpapillary plexus and a persistent connection between it and the outgrowing capillaries.

3. Two objective measurements are introduced to test the dynamics of capillary circulation: (a) *reflux time*, i.e., that time which elapses before the capillary flow ceases, when the upper arm is compressed with a blood pressure cuff, pumped up to 30 mm. above the systolic blood pressure; (b) *critical capillary pressure*, i.e., that pressure at which the flow once again reappears when the cuff in the above experiment is gradually decompressed at the rate of 10 mm. per two seconds.

4. Capillaroscopy can define the severity of the disease more accurately than the gross clinical findings.

5. The preganglionic sympathectomy has a distinct influence on the capillary picture of Raynaud's disease: (a) in 12 of 14 cases the speed of the blood flow increased; (b) in cases with a slow reflux time, the time increased, and vice versa; (c) in 10 out of 15 cases the width of the capillaries decreased; (d) the capillary permeability decreased; (e) the dilatation of the excretory ducts of the sweat glands vanished after operation; (f) these changes in the capillary picture after sympathectomy become less distinct in time; (g) the subjective symptoms of the patient are to some extent independent of the clinical picture. Some have the same typical capillary picture as before operation, even though relieved of complaints. Others show objective improvement clinically, but retain their subjective complaints, because a neurasthenia may become apparent, which may have been a part of the picture from the beginning.

THE EXCRETION OF GOLD FOLLOWING THE ADMINISTRATION OF GOLD SODIUM THIOMALATE IN RHEUMATOID ARTHRITIS*

EDWARD F. HARTUNG, M.D., JOYCE COTTER, B.A., AND
CATHERINE GANNON, B.A., M.A., NEW YORK, N. Y.

IT IS generally agreed by those who have had a large experience with gold therapy in rheumatoid arthritis that this form of treatment is followed by encouraging therapeutic results in a large proportion of patients. However, toxic reactions and untoward effects are so common and so serious that there is great urgency for an increase in our knowledge relative to the mode of action, toxicology, and excretion of gold compounds. We have previously reported¹ the marked bacteriostatic power of the serum against many common laboratory organisms which develops following the administration of gold sodium thiomalate. Similar observations were made after the administration of gold sodium thiosulfate and aurothioglucose. These effects may, but do not necessarily, throw some light on the mechanism by which beneficial results are obtained with gold therapy. We recognize that as yet the causative agent of rheumatoid arthritis has not been demonstrated, and that the disease has not been conclusively shown to be of infectious origin.

OBJECTIVE

Our objective here is to report studies on the urinary excretion of gold following the parenteral administration of gold sodium thiomalate. In view of the long duration of unfavorable reactions when they do occur, a special objective was to determine the length of time excretion through the urine con-

*From the Arthritis Clinic and the Division of Pathological Chemistry, Department of Medicine, New York Post-Graduate Medical School and Hospital, Columbia University.
Received for publication, October 24, 1940.

tinued after administration was stopped. Less complete observations were made on the gold content of the synovial fluid, stool, and saliva. We were also interested in determining the amount of gold present in the whole blood and blood serum at varying intervals, and the relationship of these levels to the urinary excretion, but these latter studies will be reported subsequently. All such studies, when coordinated with the occurrence of beneficial effects and toxic reactions, should lead to a clarification of the technique of aurotherapy.

METHOD

The method we used for the determination of urinary gold was described by Pollard² in 1937, and by Jamieson and Watson in 1938.³ Some modifications necessary to make the method applicable to the analyses of materials other than urine will be more completely described in a subsequent paper. Analysis of known samples by these methods resulted in practically 100 per cent recovery. The details observed in the collection of specimens are recorded under the separate experiments described below. Whenever possible the twenty-four-hour urine collections were started at 8:00 A.M., and the gold salt was given as near after 9:00 A.M. as possible. All patients studied were suffering from rheumatoid arthritis and the observations were made during routine treatment with gold sodium thiomalate administered parenterally in aqueous solution. As a rule, no other medication was given. The average dose of gold sodium thiomalate varied from 25 mg. once a week to 50 mg. every other day. The results of our analyses are recorded in terms of metallic gold. It is to be remembered that gold sodium thiomalate contains only 50 per cent metallic gold.

RESULTS

Experiment 1. O. J., female, aged 35 years, with rheumatoid arthritis, received weekly injections of gold sodium thiomalate after two control urinalyses had been done. These, of course, were negative for gold. Subsequently, urines were collected twenty-four hours before and twenty-four hours after the injection of the gold salt. Table I records our results.

TABLE I
URINARY EXCRETION OF GOLD FOLLOWING SUBCUTANEOUS INJECTIONS OF GOLD SODIUM THIOMALATE

CASE	DATE	ADMINISTRATION OF GOLD SALT (MG.)	VOLUME 24 HR. URINE (C.C.)	URINARY EXCRETION AS AU IN 24 HR. (MG.)
O. J., female, aged 35 years	Mar.	14-15	1,125	0
		20-21	925	0
		21-22	840	0.38
		27-28	1,000	0.08
		28-29	935	0.15
	April	3-4	1,125	0.08
		4-5	780	0.30
		10-11	860	0.13
		11-12	810	0.42
		17-18	720	0.23
		18-19	1,060	0.44
		24-25	1,000	0.18
		25-26	770	0.28
	May	1-2	800	0.24
		2-3	700	0.75
		8-9	510	0.32
		9-10	600	0.40

It will be observed that the urinary excretion of gold was less during the twenty-four hours before than the twenty-four hours after the injection of gold salt, but that this difference appeared to decrease week by week.

Experiment 2. A male, aged 38 years, was given injections up to 50 mg. every other day. It will be observed (Table II) that the urinary excretion gradually increased, reaching a maximum of 2.07 mg. During the thirteen days under observation he received a total of 280 mg. of gold salt (140 mg. of metallic gold). He excreted through the urine during this period (allowing an estimated excretion of 0.40 for June 15 to June 16, when the urinary determination was omitted) a total of 12.83 mg. of metallic gold, or roughly 9 per cent of his intake of metallic gold during this period. Serum levels were determined on four days, the results varying from 0.22 to 0.50 mg. per cent. On June 18 the serum content was 0.50 mg. per cent and the synovial fluid content was likewise 0.50 mg. per cent. For three days, starting June 18, carmine-marked stools were collected. It was found that during this three-day period, the patient excreted through the stool only 0.66 mg. It will be observed that the urinary loss during this three-day interval was 4.27 mg. The stool excretion, therefore, was very much less in proportion to the urinary excretion during these three days.

TABLE II

URINARY AND STOOL EXCRETION OF GOLD, AND GOLD CONTENT OF SERUM AND SYNOVIAL FLUID FOLLOWING SUBCUTANEOUS INJECTIONS OF GOLD SODIUM THIOALATE

(Male, Aged 38 Years)

24-25	50	1,700	2.07	0.44		

Experiment 3. M. W., female, aged 38 years, had received 330 mg. of gold sodium thiomalate previous to the excretion studies we made. Subsequently, 25 mg. of gold salt were given every seven days. Table III records the daily urinary excretion of metallic gold. In this instance, the excretion became relatively fixed, varying between 0.17 and 0.51 mg. in twenty-four hours. From these observations, one might suggest that there was a renal threshold for gold excretion, but the evidence of Experiment 2 (where the excretion gradually increased) tends to contradict this impression.

During the fourteen days from April 26 through May 10 this patient received 50 mg. of gold salt or 25 mg. of metallic gold. She excreted through the urine during this period (assigning an estimated average of 0.33 mg. for April 27 when the determination was omitted) a total of 4.35 mg. of gold, or 17.2 per cent of the intake. This proportion is larger than that found in Experiment 2 where the percentage of excretion was 9 per cent.

Experiment 4. It was important to know how long the urinary excretion of gold continued after the administration of gold salt had been discontinued. Table IV records the gold content of the urine at varying days from 60 to 300 after the cessation of therapy. In Case 5 there was 0.04 mg. of gold in the urine on the 210th day, 0.03 mg. on the 240th day, but no gold on the 270th day. In Case 2, 0.01 mg. was found on the 300th day. All observations made show that gold is still excreted long after the administration has been discontinued.

Experiment 5. A few observations were made on the metallic gold content of the stool. Stools were appropriately marked with carmine in each case. It will be observed (Table V) that the excretion of gold through the stool varied between 0.22 and 0.65 mg. in twenty-four hours.

Experiment 6. In two instances (Table VI) saliva was collected during the course of gold sodium thiomalate administration. In neither of these instances was metallic gold found in the saliva.

Experiment 7. S. P., female, aged 35 years, had never received gold before the institution of these observations. After she had received 330 mg. of gold salt, she developed a slight dermatitis under both axillae, which may or may not have been due to gold. However, the gold administration was discontinued. Subsequently from July 17 through July 29, the

daily urinary excretion was determined (Table VII). In this case, as in Experiment 3, the urinary excretion seemed rather fixed. After the seventh day of this relative fixation of excretion, we were interested in observing the effect of sodium bicarbonate on the rate of excretion. Up to 15.6 Gm. were administered by mouth daily. It will be observed that from the eighth to the thirteenth day, the urinary excretion continued relatively constant, the administration of sodium bicarbonate apparently having no effect in this respect.

Our object here was to observe whether sodium bicarbonate had the same accelerating effect on the excretion of gold as it has been found to have on the excretion of lead. These studies are being extended and will be reported more fully at a later date.

CONCLUSIONS

1. Following the subcutaneous administration of gold sodium thiomalate in patients with rheumatoid arthritis, metallic gold can be consistently recovered from the urine, and the twenty-four-hour excretion determined.

2. In two instances the urinary excretion of gold approximated 9 and 17.2 per cent of the intake of gold during the period of observation.

3. Gold was found in the urine from 60 to 300 days after administration of gold sodium thiomalate had been stopped.

4. The gold content of the stool in three instances ranged from 0.22 to 0.65 mg. in twenty-four hours.

5. No gold could be recovered from the saliva in the two instances studied.

6. As far as our observations were extended, the administration of sodium bicarbonate by mouth had no quantitative effect on the excretion of gold in the urine.

STUDIES IN BACTERIOPHAGE VI

THE EFFECT OF SULFAPYRIDINE AND SULFANILAMIDE ON STAPHYLOCOCCI AND *B. COLI* AND THEIR RESPECTIVE BACTERIOPHAGES*

HELEN ZAYTZEFF-JERN, M.D., AND FRANK L. MELENEY, M.D., NEW YORK, N. Y.

INTRODUCTION

IN A PREVIOUS publication¹ we reported the effect of a large series of anti-septics, used in surgical practice, on staphylococcus, *E. coli*, and *B. pyocyaneus* bacteriophages. We found that sulfanilamide (prontosil and prontylin) and its derivative, sulfapyridine, were the only substances tested which exerted no significant influence on the lytic phenomenon.

In a number of later experiments with weaker phages, these drugs seemed to have an adjuvant effect upon the action of bacteriophage, but they had no appreciable effect on phages of high titer and lytic ability. This suggested that the combination of phage and one of these drugs may be used in those cases in which the causative organism was partially resistant to phage or in mixed infections where each may have a specific action.

EXPERIMENTAL TECHNIQUE

Our stock mixture of staphylococcus phages S1, and individual phages 43† and BH‡ were tested against 50 strains of staphylococci obtained from various sources and possessing various degrees of phage susceptibility, with and without sulfapyridine and sulfanilamide.

Our stock mixture of *E. coli* phages B4 and individual phage MK were likewise used in conjunction with these two substances when propagated against 45 strains of *E. coli* of various degrees of susceptibility.

The technique of the experiments was in general the same as in our previous work.¹ All lysis tests were carried out in 5.5 c.c. of Savita broth. Plating of lysed tubes on 5 per cent sheep's blood agar indicated the presence or absence of surviving bacteria. The titer of the phages was determined by making decimal dilutions in saline, adding bacteria and then counting the plaques when these dilutions were transplanted and incubated on 1 per cent plain agar plates. Generally, in carrying out phage susceptibility tests, 0.05 c.c. of staphylococcus phage, or 0.25 c.c. of *E. coli* phage, were used in 5.5 c.c. of Savita broth, together with approximately 50 to 60 million bacteria per cubic centimeter. Variations from this technique are indicated in certain experiments.

Sulfapyridine and sulfanilamide were used in a 10^{-4} dilution (1:10,000), which is about the highest concentration which these substances ordinarily reach

*From the Bacteriological Research Laboratory of the Department of Surgery, College of Physicians and Surgeons, Columbia University.

Received for publication, June 27, 1940.

†Obtained in 1933 from Dr. Bulgakov.

‡Obtained in 1933 from Dr. Gratia.

in the circulation of treated patients. In order to obtain the necessary concentration, 0.5 c.e. of the 10^{-3} dilution (1:1,000) of these drugs in Savita broth (sterilized by boiling for five minutes) was added to 5 c.e. of Savita.

RESULTS

A. The Effect of Sulfapyridine (SP) and Sulfanilamide (SN) on the *Staphylococcus Bacteriophage* Phenomenon

I. *The Degree and Permanency of Bacteriolysis Both With and Without SP and SN.*—S1 phage (slightly weakened by forty-eight-hour standing at room temperature) was set up with 15 strains of staphylococci, most of which were somewhat resistant to the phage. Two series of tubes containing 5.5 c.e. of Savita plus sulfapyridine SP (1:10,000) were employed. One series was inoculated with 0.05 c.e. of phage and 0.1 c.e. of an eighteen-hour Savita broth culture of bacteria (making about 50 million per cubic centimeter), and the other series with bacteria alone. Two series of 5.5 c.e. of Savita without sulfapyridine, inoculated in a similar manner, served as controls. The results of the test are shown in Table I. It is seen that after four and a half hours' incubation,

4+ = Complete clearing.

4± to ± = Different degrees of clearing.

- = No lysis.

tion, the degree of clearing or growth in corresponding tubes with and without SP was essentially the same. After twenty-two and a half hours' incubation, four cultures, only partially clear in the absence of sulfapyridine, were completely clear in the corresponding tubes containing sulfapyridine. After five days' incubation five cultures which were cloudy in the absence of sulfapyridine were completely clear (4+) in the corresponding tubes containing sulfapyridine, and two others, which in the absence of SP showed 2+ lysis, were almost clear (4±).

The experiment was repeated with the individual phage No. 43 and eight strains of staphylococci, and similar results were obtained. This phage produced complete visible lysis of all these strains in the test tubes without SP or SN in twenty-four hours, but five of the cleared cultures yielded growth upon plating and these tubes became cloudy within seventy-two hours. The corresponding tubes containing phage and either SP or SN not only became clear, but also gave no growth upon plating, and remained clear for fifty days at room temperature when examined last.

In attempting to explain these results, the question naturally arose whether this effect was attained through an increase in the lytic power of the bacteriophage or whether it was due to some effect upon the bacteria. In the series of experiments which follow we have attempted to answer these questions.

II. *The Significance of Bacterial Concentration on the Bacteriolytic Phenomenon Both With and Without Sulfapyridine and Sulfanilamide.*—Staphylococcus phage mixture S1 and single phage BH were tested against four strains in amounts of 0.1 c.c. and 0.35 c.c., and 0.6 c.c. of an eighteen-hour Savita culture, which made suspensions of approximately 50 million, 175 million, and 300 million bacteria per cubic centimeter (Table II). It is evident that with both SP and SN the small bacterial inoculations gave complete clearing with phage with all strains, while the higher bacterial concentrations did not.

III. *The Effect of Sulfapyridine and Sulfanilamide Upon the Titer and Lytic Power of Staphylococcus Bacteriophage.*—

1. *The effect after a single twenty-four-hour passage as compared with five subsequent twenty-four-hour passages:* S1 phage was propagated on nine different strains, and No. 43 phage on three of these nine. After one passage seven of nine showed no appreciable difference between the titers of the Savita broth as compared with Savita plus sulfapyridine. In two, however, there was an appreciable lowering of titer in the presence of the drug. After five passages there was no increase or decrease in the titer or lytic ability of these phages, and no appreciable difference between the Savita phage and those containing SP and SN.

2. *The effect of storage in the refrigerator after a single passage:* Bacteriophages S1 and 43 were propagated at the expense of nine and three strains, respectively, in Savita broth both with and without SP or SN. They were then filtered and placed in the refrigerator. Titrations were carried out immediately, and again after six days, ten days, and one month. The titer was essentially

unchanged throughout this period both with and without SP and SN, except for two phages with SP, which were of definitely lower titer after one passage and remained at this titer throughout.

3. *The effect of SP and SN on the adaptation of staphylococcus bacteriophage to partially or completely resistant staphylococcus strains:* Six strains of staphylococci, four of which were partially resistant and two completely resistant to phage, were used for the repeated propagation of phage in Savita containing sulfapyridine and sulfanilamide. The propagated phages were then applied to the original cultures, and it was found that their lytic power had not increased.

IV. *The Effect of Sulfapyridine and Sulfanilamide on Staphylococci in the Absence of Bacteriophage.*—

1. *The effect on five consecutive twenty-four-hour passages in Savita both with and without sulfapyridine and sulfanilamide:* In this experiment, 0.1 c.e. and 0.01 c.e. of an eighteen-hour culture of eight strains of *Staphylococcus aureus* (three susceptible, two partially susceptible, and three resistant to phage) were inoculated into tubes containing 5.5 c.e. of Savita, Savita plus SP, and Savita plus SN, respectively, and incubated for twenty-four hours. One-tenth cubic centimeter of these cultures was then transplanted into similar media on four successive days. Readings were made after three, six, and twenty-four hours of incubation, and the clear tubes were plated for possible growth. Results of the effect of SP and SN on the tubes inoculated with 0.01 c.e. of these eight cultures and their four subcultures in respective media are presented in Table III. It is seen that all three strains which were completely resistant to phage were immediately inhibited by both SP and SN, and two of these were completely destroyed by SP in the course of the passages. On the other hand, the five strains of staphylococci which were completely or partially susceptible to phage, suffered only a transitory inhibition by SP and were practically not affected by SN.

2. *The effect of one twenty-four-hour passage on varying dilutions of bacteria:* In an attempt to study the action of SP and SN (dilution 1:10,000) on *Staphylococcus aureus* more closely, 0.1 c.e. of dilutions 10^{-2} and 10^{-4} of eighteen-hour cultures were taken beside the dilutions made with 0.1 c.e. and 0.01 c.e. of undiluted culture. In order to ascertain the number of bacteria per cubic centimeter of the suspension and its increase or decrease after contact with the drugs, a loopful (approximately 0.01 c.e.) of the highest dilution was plated immediately, and again after five and twenty-four hours of incubation. Growth in liquid media was followed after five, twenty-four, and forty-eight hours, and the clear tubes containing SP and SN were observed during two weeks of incubation. Fifteen strains of staphylococci, of which five were susceptible to phage, seven partially susceptible, and three entirely resistant, were used. Representative results of these experiments are presented in Table IV. An immediate plating of 0.01 c.e. of all the tubes which had been inoculated with 0.1 c.e. of the 10^{-4} dilution of eighteen-hour cultures of all 15 strains showed two to 34 colonies. After five hours of incubation similar transplants showed that the number of colonies on all plates increased considerably. However, in the presence of SP there were only one-half to one-fourth as many colonies as in plain Savita. After

++++ = Normal growth in Savita and on plating.

* = Growth appeared after several days of incubation

IC = Innumerable colonies.

twenty-four hours of incubation the 10^{-4} dilution of each of the 15 cultures grown in SP displayed no visible growth. Upon further incubation it was noted that all but three grew eventually. Of these three destroyed strains, two were resistant to phage and the third was phage susceptible. All three strains when inoculated in 0.01 c.c. amounts of undiluted culture were again the only ones which gave no visible growth in SP tubes.

The effect of SN, although generally lower, was most pronounced in regard to the same three strains.

Out of seven strains used in all of the experiments, which were completely resistant to phage, six proved to be most susceptible to the bacteriostatic and bactericidal effect of SP and SN.

Of all 15 strains susceptible and partially susceptible to phage, only one showed a susceptibility to SP and SN similar to that of phage-resistant strains. Although the others were always affected by SP, they were destroyed by this drug only when they were in high dilution. When the bacteria were not destroyed within twenty-four hours, visible growth always developed upon further incubation.

V. Morphologic Changes Under the Action of Sulfapyridine and Sulfanilamide.—SP and SN not only inhibited the growth of certain strains in broth, but also altered to some extent the appearance of colonies when subcultured on a blood agar plate. Changes in size, shape, pigment production, and hemolysis were observed. Some colonies were degenerated and indented or pin point in size, presenting the appearance similar to changes after contact with bacteriophage. Some were normal yellowish, some were white, others were semi-transparent, and still others were bright yellow. Some colonies were normally hemolytic, others were nonhemolytic, while a few were surrounded by a large zone of hemolysis. One culture treated with SN showed colonies surrounded by a double zone of hemolysis. Microscopically, the cultures grown in SP and SN showed the following morphologic changes: The size of some of the cocci was increased for two to six times. They were not as sharply outlined, the staining was less deep, and some seemed to be encapsulated.

VI. Effect of SP and SN on Phage Susceptibility of Staphylococci.—The phage susceptibility test on six strains of *Staphylococcus aureus*, which was carried out after twenty-four and forty-eight hours' contact of the bacteria with SP and SN at 37° C., showed no change in phage susceptibility of any of the strains. When the susceptibility tests were carried out after five days' contact with SP and SN, the results were inconclusive. Some strains became more resistant and others became more susceptible. Constant results could not be obtained.

B. The Effect of Sulfapyridine (SP) and Sulfanilamide (SN) Upon the E. coli Bacteriophage Phenomenon

I. The Degree and Permanency of Bacteriolysis Both With and Without SP and SN.—The effect of SP and SN upon *E. coli* and *E. coli* phages was studied along the same lines as the experiments with staphylococci. Table V presents results of the susceptibility tests of *E. coli* phage mixture B4 against ten strains of *E. coli* carried out with 0.1 c.c. of an eighteen-hour culture and 0.25 c.c. of

phage in 5.5 c.c. of Savita broth with and without SP and SN (dilution of 1:10,000). The effect of SP and SN upon the bacteria, in the absence of phage, was noted at the same time. From this table one can see that phage in Savita alone cleared seven of ten cultures within four hours, but only three maintained visible clearing for twenty-four hours, and two of these developed growth upon further incubation. The same phage set in Savita, plus SP, produced complete clearing after four hours of the same seven strains, and maintained it for twenty-four hours. Four of these strains maintained lysis for a week in the incubator, while three became cloudy. Two other cultures, which were partially cleared after four hours and remained so after twenty-four hours, later became a little more cloudy in the presence of SP. One of the ten cultures was completely resistant to phage and failed to undergo any lysis even in the presence of phage and SP. Contrary to the results obtained with staphylococci, the addition of SN to *E. coli* phage-bacteria mixtures had much less effect than SP.

TABLE V

4+ = Complete lysis.

3+ to 1+ = Various degrees of lysis.

± = Doubtful.

- = No lysis or normal growth.

Table V also shows that the SP alone produced a marked bacteriostatic effect upon most of the strains. The effect of SN was less than SP both in degree and extent.

The experiment was repeated with 35 more strains of varying resistance to phage, and similar results were noted. It was found that there was a definite correlation between the potency of phage against a given strain and the degree and duration of lysis attained by phage upon addition of SP. The cultures which were not completely cleared by phage in plain Savita within eight hours, showed, in Savita plus SP, a greater degree of lysis, but still it was not complete. The cultures which were completely cleared by phage in plain Savita within eight hours, but by twenty-four hours showed a secondary growth, were maintained clear in SP tubes for a period of twenty-four hours or longer. In other words, the SP prevented or delayed secondary growth.

Furthermore, the cultures that remained clear in Savita for at least twenty-four hours but gave growth upon plating on blood agar, were completely destroyed in the presence of SP. The strains that were permanently destroyed by phage in Savita were, of course, in no way affected by the addition of SP.

II. *The Effect of Sulfapyridine and Sulfanilamide on the Titer, Lytic Ability, and Range of Activity of E. coli Phages.*—Bacteriophage mixture B4 and the individual bacteriophage MK were employed in these experiments and were propagated at the expense of three different strains. All these strains were susceptible to phage B4, but only two of the three were susceptible to phage MK, the third being partially susceptible. The titrations were carried out after one and after five twenty-four-hour passages. At the same time, the first group of phages, incubated for twenty-four hours in the presence of SP, SN, and in plain Savita, were placed in the refrigerator and were titrated after five days, two weeks, one month, and six months. When titrated after twenty-four hours' contact with SP and SN, both B4 and MK phages, propagated on three susceptible strains, suffered no drop of titer, but in the presence of one of these drugs increased tenfold instead of one hundred times as did the control. However, the effect of SP was quite pronounced when bacteriophage MK was propagated at the expense of the partially susceptible strain. In this instance, while the titer of the bacteriophage was lowered to 10^4 in Savita and Savita plus SN, phage developed normally and reached a titer of 10^7 in the presence of SP. This experiment was repeated with the same results, and in general confirmed similar findings obtained with staphylococcus bacteriophage when these were propagated on the partially susceptible strains.

The titration of B4 and MK after five twenty-four-hour passages showed no significant differences in the titer of the phages, whether propagated on any of the three strains in SP, SN, or plain Savita. There was also no significant decrease in the original titer after two weeks, or after one month of contact with the SP and SN in the refrigerator at 4° C. A slight decrease of the titer of phage was occasionally noticed after six months of contact. These results fully agreed with similar tests with staphylococcus bacteriophages.

The lytic ability and the range of activity of *E. coli* phages was usually unaffected by contact with SP, and only when phage was propagated on partially susceptible strains was the phage with SP slightly higher than its Savita control.

Innumerable attempts to increase the lytic ability of *B. coli* phages to partially susceptible strains by adding SP ended in complete failure.

III. *The Effect of Sulfapyridine and Sulfanilamide on E. coli Strains and Their Subsequent Susceptibility to Bacteriophage.*—The same technique was used as with staphylococcus cultures. In no case was there complete destruction of the strain in the course of several passages when the undiluted culture was used and there was no significant difference between the phage-susceptible and phage-resistant strains in their degree of sensitivity to the effect of SP. The effect of SN was even less than that of SP.

On the other hand, when the experiments were carried out with an inoculation of 0.1 c.c. of undiluted bacterial culture and compared with the 10^{-2} and 10^{-4}

dilutions of the bacterial cultures, it was found that SP occasionally destroyed the two higher dilutions, but did not significantly affect the undiluted cultures (see Table VI). The undiluted cultures were in general more susceptible to the bacteriostatic action of SP than the staphylococci, but the higher dilutions were less susceptible to the *bactericidal* action of SP than the staphylococci. The effect of SN again ran parallel with SP but was always less pronounced.

TABLE VI

EFFECT OF 10-4 DILUTION OF SP AND SN ON VARIOUS AMOUNTS OF *B. coli* IN SAVITA BROTH IN THE ABSENCE OF BACTERIOPHAGE

Colony count was made by spreading approximately 0.01 c.c. of the tube containing 0.1 c.c. of dilution 10⁻⁴ of eighteen-hour culture in 5.5 c.c. of Savita, Savita plus SP, and Savita plus SN upon a quadrant of blood plate.

+++ = Normal growth on plating or in Savita.

- = No growth on plating or Savita.

+++ to ± = Various amounts of growth on plating and Savita, ± being the smallest and +++ the most abundant.

Neither SP nor SN produced any significant morphologic changes in regard to size, form, or other characteristics of the colonies of *E. coli* or significant microscopic morphologic changes in the organisms themselves.

E. coli strains, which were subcultured or maintained up to five days in the incubator in the presence of SP and SN, showed practically no change in their susceptibility to phage.

C. *The Effect of Various Concentrations of Sulfapyridine Upon the Bacteriophage Phenomenon*

In order to ascertain whether concentrations other than 1:10,000 (10 mg. per cent) of SP (which bacteriophage might encounter in the body) exerted a similar effect upon bacteriophage and bacteria, dilutions of 1:1,000, 1:50,000, 1:200,000, and 1:500,000 were studied. The action of these dilutions of SP upon *E. coli* and staphylococcus cultures was tested simultaneously and compared with the dilution 1:10,000. This was carried out with eight strains of each species in the presence and absence of bacteriophage. The experiments showed that SP dilution 1:10,000, in conjunction with bacteriophage, was somewhat more effective than 1:1,000 or 1:5,000 dilutions. The dilutions 1:200,000 and 1:500,000, on the other hand, had absolutely no effect upon the bacteriophage phenomenon.

SUMMARY

We are reporting herewith a study of the effect of sulfapyridine and sulfanilamide upon staphylococcus and *E. coli* cultures and their respective phages with regard to the lytic phenomenon. This study was carried out with three staphylococcus phages against 50 strains of staphylococci and two *E. coli* phages, together with 45 strains of *E. coli*.

1. The addition of sulfapyridine in the dilution 1:10,000 to staphylococcus and *E. coli* phage suspensions with partially susceptible bacterial strains definitely increased the bacteriolysis and often resulted in complete destruction of all bacteria. The best results were attained with bacteriophages capable of maintaining lysis for at least eighteen to twenty-four hours, and with an initial bacterial inoculation not exceeding 50 million bacteria per cubic centimeter.

2. The use of sulfapyridine with weaker phages, which maintained lysis for less than eighteen hours with 50 million bacteria per cubic centimeter without the drugs, usually resulted in prolongation of lysis up to several days, but complete sterilization was seldom attained.

3. Dilution 1:10,000 (10 mg. per cent) of sulfapyridine produced the most favorable effect upon the bacteriophage phenomenon. The effect of dilution 1:1,000 and 1:50,000 was slightly below that of 1:10,000 SP dilution. Dilutions 1:200,000 and 1:500,000, however, did not exert any effect upon the bacteriophage phenomenon.

4. Both sulfapyridine and sulfanilamide exerted a bacteriostatic as well as a bactericidal effect on *Staphylococcus aureus* and were capable of destroying dilute bacterial suspensions, usually not exceeding 5,000 per cubic centimeter. The effect of SP was much greater than that of SN, and this was further shown by its pronounced activity against higher bacterial concentrations. The rapidity, duration, and degree of bacteriostatic and bactericidal effect varied for each strain and was most pronounced and complete against six of seven phage-resistant strains.

5. Both sulfapyridine and sulfanilamide were capable of producing macroscopic morphologic changes with regard to the size, shape, pigmentation, and hemolytic properties of the colonies of staphylococci and also certain microscopic changes on the organisms themselves.

6. Both SP and SN produced some inconsistent changes in the state of phage susceptibility of completely and partially phage-susceptible strains, whereas they had no effect on the state of phage resistance of completely phage-resistant strains.

7. Sulfapyridine possessed a pronounced bacteriostatic and bactericidal effect upon *E. coli*, and was capable of destroying a suspension not exceeding 5,000 bacteria per cubic centimeter of phage-susceptible and partially susceptible strains. When confronted with heavy suspensions of these strains, its bacteriostatic effect was usually more pronounced than on similar suspensions of staphylococci; however, its bactericidal power on *E. coli* was less than on staphylococci.

8. Sulfanilamide caused no significant change in the degree of bacterial lysis of *E. coli* strains with phage, and had no significant bacteriostatic or bactericidal effect on *E. coli* cultures.

9. Sulfapyridine and sulfanilamide added for the first time to staphylococcus and *E. coli* phages propagated on susceptible bacteria occasionally decreased the bacteriophage titer (not more than ten times) and its lytic power. However, upon repeated passages or prolonged contacts the titer and lytic activity of phage usually were re-established to their original level. Preservation of phage in 1:10,000 dilution of SP for six months did not significantly change its original titer. However, the adaptation of phage to partially susceptible strains was more successful in the absence of SP, indicating that SP prevented an increase of potency of phages.

CONCLUSIONS

1. Sulfanilamide and sulfapyridine do not interfere significantly with the lytic action of specific bacteriophage on *Staphylococcus aureus* or *B. coli* in vitro when these organisms are completely susceptible to the corresponding phage.

2. With strains of these organisms, which are not completely destroyed by the lytic action of the corresponding bacteriophage, the associated use of sulfapyridine, and to a less extent sulfanilamide, frequently completes the destruction of the bacteria in vitro—a synergistic effect.

3. Sulfanilamide or sulfapyridine may be used together with specific bacteriophage in the treatment of staphylococcus or *B. coli* infections. There may be a synergistic effect with these combinations in vivo.

4. Bacteriophage is generally more bactericidal on the corresponding staphylococci and *E. coli* than either sulfanilamide or sulfapyridine.

5. In the treatment of staphylococcus and *E. coli* septicemia, the use of potent bacteriophage, when it is available, should not be delayed because of the attempted use of sulfanilamide or sulfapyridine.

We wish to acknowledge the technical assistance of Miss Olga Mordvin and Mr. John T. Goodner.

VARIATION OF THE ORGANIZED SEDIMENT FOLLOWING PYRIDIUM ADMINISTRATION IN URINARY INFECTIONS*

A TECHNIQUE FOR THE STUDY OF THE ORGANIZED SEDIMENT VOLUME

LEO D. BRAITBERG, B.S., CHICAGO, ILL.

IN THE papers by Reynolds, Wilkey, and Choy,⁴ and Morrissey and Spinelli,² the effect of phenylazo-alpha-alpha-diamino-pyridine monohydrochloride on the symptomatology of urinary infections was adequately evaluated. This study is restricted to observations of the effect of pyridium on the variation in the amount of the organized urinary sediment. Although it was undertaken primarily for the purpose of sediment study, observations as to burning, dysuria, and nocturia were also carefully noted in an attempt to correlate the reduction of the urinary sediment with a decrease in the severity of these symptoms.

The terms "organized" and "unorganized" sediment are used as defined by Hawk and Bergeim.¹ In this paper, granular, epithelial, blood, and other pathologic casts will not be a part of the organized sediment. The volume of the organized sediment was selected for study because the total sediment, which may consist to a great extent of the unorganized sediment, bears no direct relationship to the severity of the infection. In a twenty-four-hour urine collection the amount of the unorganized sediment is a function of the diet, the pH, and the external temperature. The amount of unorganized sediment is also a function of the urease enzyme of the bacteria, which acts at various rates, depending upon the amount of urease, the amount of urea, the amount of buffer phosphates, the ionic strength of the solution, the pH, and the temperature. Thus a voluminous precipitate of salts may occur even if only small amounts of pus cells, epithelial cells, and bacteria are present. Since the unorganized sediment precipitate depends upon many factors apart from the infection, it is unsatisfactory material to work with if one is interested in studying the effect of a drug in clearing up infections. Therefore, in this report, the aim is to exclude, as much as possible, the effect of unorganized sediment from the determinations of the organized sediment volume.

While this work was in progress the paper of Morrissey and Spinelli² was published in which tentative studies of sediment variation following pyridium administration were made. No mention was made as to control or technique of their sediment studies. They report "a reduction of one-half to two-thirds of the amount of urinary sediment in operative cases when the drug was used." Although pyridium was given to these patients preoperatively and postopera-

†Commercially available under the trade name "pyridium."

tively, it is not specified whether the sediment studies were made preoperatively, postoperatively, or both. Since it is stated that these patients were "operative," we assume that postoperative determinations of sediment were made.

Obviously, sediment studies made soon after an operation are comparatively less significant, since the operation is designed to relieve the primary cause from which the infection developed. Thus the condition should clear up spontaneously. Although the drug may do it faster, it is impossible to separate the factor of spontaneous resolution due to better drainage from that of the action of the drug. Only those cases in which infections persist for months after operation were considered suitable for the sediment studies reported here.

In selecting material for this study, the following postulates were established and the choice of patients were so made:

1. Low nonprotein nitrogen. Patients with a high nonprotein nitrogen or those who show extensive kidney damage cannot properly eliminate the educt.*
2. Demonstrable pus cells in a fresh urine specimen—6 to loaded per high-power field.
3. No granular, epithelial, or blood casts, and not more than a trace to 1+ of albumin. These findings, if present, will give false values to the sediment determinations.
4. No gross hematuria, the variation of which from day to day gives sediment values that may have no relation to the severity of the infection.
5. Female patients only can be used:
 - (a) Those who have only a small number of vaginal epithelial cells in the urine during the nonmenstrual period.
 - (b) Those past the menopause.
 - (c) Those who would cooperate in reporting menstrual cycle, so that determinations would not be made during that period.
6. If the patient is a postoperative case, sediment studies should not be started unless the infection persists one or two months after the operation for reasons given in the discussion by Morrissey and Spinelli.³
7. Patients who are being sounded cannot be used for sediment studies, since soundings injure the tissues and increase sediment.

PROCEDURE

The twenty-four-hour urines were collected in brown bottles of from 2 to 4 liter capacity, depending upon the output of the patient. Five cubic centimeters of a 2 per cent alcoholic solution of thymol were added, and the bottle was rotated so that all of its interior was coated by the solution. This is preferable to adding crystals, since the crystals interfere with the reading of the sediment in the calibrated end of the centrifuge bottle. The daily urine volume was measured, so that results could be expressed in both sediment per 100 c.c. and total sediment. A preliminary twenty-four-hour collection without pyridium

*Pyridium elimination product.

was tested for organized sediment by the process described below. For approximately two weeks sediment determinations were run on the subsequent twenty-four-hour periods. This was done in the same manner as that of the preliminary specimen, using pyridium in dosages of 600 to 900 mg. per day.

The twenty-four-hour specimen was well shaken and a portion of about 150 c.c. was placed in a beaker. The pH was adjusted to 5.5 ± 0.2 using 1:1 hydrochloric acid or 1:1 ammonium hydroxide solution. Nitrazine paper was used as the indicator. The pH of the urine was checked with a quinhydrone electrode, and the results agreed very well with the nitrazine paper.

In the case in which the twenty-four-hour urine was at a pH of 5.5 or lower, an excess of ammonium hydroxide was added until a pH of 7.5 to 8.0 was reached, after which the urine was then re-acidified to a pH of 5.5. This was done to dissolve the conjugated pyridium elimination product which sometimes precipitates at these pH values on standing for twenty-four hours and also to dissolve any uric acid which might have been precipitated.

The pH 5.5 was selected because this is near the pH at which urine is voided in normal persons and for the reasons given in the following discussion. At this pH the calcium phosphates, magnesium ammonium phosphates, calcium carbonates, and most of the ammonium urates are dissolved. Thus almost all the salts on the alkaline side which might occupy a very large volume and give false information to the determination of the "organized" sediment will be completely avoided. The only salt that will not dissolve readily at this pH is calcium oxalate, and while it is present in many cases, it contributes a negligible amount to the volume of the precipitate. A pronounced case of oxaluria was not seen during the course of these studies, even though the normal cases were medical students who were under great stress and anxiety due to scholastic examinations.

On the acid side, between pH 5.5 and pH 7, there is a danger of some sodium urate² precipitation, but the patients usually have an output of about 2,000 c.c., and in twenty-four hours, at room temperature, very little of the sodium urate will precipitate unless the patient has a fever.

The determinations of the sediment were run in Goetz phosphorous centrifuge bottles with a volume of 100 c.c. and a tip of 1 c.c. capacity, and calibrated in 0.05 c.c. graduations from which estimations of ± 0.01 c.c. could be made. The specimens adjusted to a pH of 5.5, as indicated above, were centrifuged for fifteen minutes at the rate of $1,800 \pm 300$ r.p.m. At this speed, for the given time, variations in sediment volume are negligible for a few minutes before or after the fifteen minutes' interval, so that it can be concluded that the packing of the sediment has reached a relatively constant point. The nebeccula, which consists of mucin, is insoluble at this pH. It descends in the centrifuge bottle as a light voluminous opalescent flocculation and is not to be considered as a part of the organized sediment. The separation between the nebeccula and the solid opaque organized sediment is usually sharp, so that no difficulty in reading the sediment is encountered. In the case that the separation is not distinct, an error in reading of about ± 0.03 instead of the 0.01 is given, and the best estimation possible is made. This type of difficulty does not occur very often.

It is granted here that in a twenty-four-hour specimen, especially in alkaline solution, cytolysis tends to decrease the sediment volume, but a compensating factor of protein swelling tends to keep this error down. Since the sediment in succeeding twenty-four-hour samples of the same patient is compared, this error will be relatively constant over a short period.

Graph 1.—Distribution of 40 cases of urinary infections with regard to organized urinary sediment variation per 100 c.c. of urine following pyridium therapy for approximately two weeks.

While this work was undertaken principally for the purpose of sediment study, the symptoms of burning and nocturia were carefully noted. In almost all cases in which these symptoms were reported, there was a marked decrease in nocturia and in the severity of the burning following the administration of pyridium. Some cases were spectacular with respect to the rate at which a severe burning would disappear, giving evidence of the reported analgesic power of pyridium. In some of these cases a severe burning would be completely gone after twenty-four to forty-eight hours' use of pyridium. Results such as these are a confirmation of all the clinical studies made by previous investigators. This part of the work was done in an effort to correlate the reduction and disappearance of the symptoms with a decrease in the sediment.

In Table I no attempt was made to classify the types of cystitis. Not all patients were cystoscoped. The diagnoses of those patients who were not cystoscoped were made on the basis of symptomatology and demonstrable pus cells in a fresh urine specimen. Undoubtedly there were a few cases of pyelocystitis in this group. The symptoms of burning, dysuria, and nocturia are listed opposite the percentage of reduction to facilitate comparison of the symptomatology changes with the reduction in sedimentation per 100 c.c. Where

*The percentage of reduction of the total sediment would give a result similar to Table I. Because of errors in volume, inherent in the collection of twenty-four-hour specimens from hospital and ambulant patients, The author feels that the expression of the results in sedimentation per 100 c.c. is more justified and better controlled than the total sediment.

M = male.

F = female.

inc. = increase.

there is a line through the space or spaces in the symptomatology columns, no information was available. *Gone* means that symptoms were present and have completely disappeared. *Less* means symptoms were present and the severity has decreased considerably. *Same* means that symptoms were present and that they have not improved. *None* means that symptoms were not present. In no case was the severity of the symptoms increased following pyridium administration. Other symptoms recorded were not put on the chart due to space limitations. Wherever the expression "sed. per 100 c.c." occurs, it will be understood to mean cubic centimeters of sediment per 100 c.c. of urine.

COMMENTS

Table I and Graph 1 show strikingly the effect of pyridium on the reduction in the amount of organized sediment in cases of urinary infections. Eighty per cent of these cases show a decrease in sediment of 50 per cent or more. In those cases in which observation of burning and dysuria were recorded, 95 per cent showed a decrease in the severity or a disappearance of these symptoms. As can be seen from the chart, a good correlation exists between the reduction of the sediment and a decrease in the severity of the symptoms. In a few cases an improvement of the symptomatology took place without a corresponding decrease in the sediment. Normal persons do not have any appreciable organized sediment before or after pyridium.

SUMMARY

1. A technique has been presented for the determination of the organized urinary sediment volume.
2. Normal persons have a very low organized sediment before and after pyridium administration, between 0.0 and 0.02 c.c. per 100 c.c.
3. Pyridium is very effective in reducing the organized sediment in cases of urinary infection, especially cystitis and pyelonephritis.
4. With very few exceptions the reduction of the organized sediment is accompanied by a decrease or disappearance of the subjective symptoms.

THE MODE OF ACTION OF BRAN*

I. EFFECT OF BRAN UPON COMPOSITION OF STOOLS

BERNARD FANTUS, M.S., M.D., AND WILLI FRANKL, CHICAGO, ILL.

INTRODUCTION

THE extensive use of bran as a laxative and in diets justifies an inquiry into its various properties. This report deals mainly with the physical and chemical qualities of bran stools. It is aimed to discover the mode of action of bran and to elucidate, as far as possible, the effect the alimentary tract has upon bran and the effect bran has upon the alimentary tract.

METHOD OF STUDY

These investigations were carried out on approximately 200 healthy persons, for the most part male medical students between 20 and 30 years of age. A few healthy women subjects were also used.

To make the studies of practical value these persons were placed on uncontrolled and unrestricted diets, just as are the public consumers of bran. The individuals collected their stools in specially prepared asphalt paper bags† for three to six days (prebran period). This control period was followed by a second period, which varied in different experiments from three to fourteen days, during which time one ounce of bran (Kellogg's "All-Bran") was added to the daily diet (bran period). A third period of several days followed (after-bran period). All persons had normal bowel habits; stools were obtained regularly every day with very few exceptions.

At present the only consistent criterion of the laxative action of bran is the change in stool weight. Whenever this has been definitely increased, we speak of laxative action. When the weight is decreased or not changed, it is spoken of as lack of such action. It should be admitted that this criterion is not the only one. Bulk is perhaps more important, but it has not been possible to measure it accurately. The consistency of the stool may be still more important for it may possibly be more constantly affected by bran, and "penetrometric" studies to investigate this matter are reported. The frequency of the stools is important, but it was not possible to secure a record that gave significant results in these normal persons of fixed habits. The rapidity with which the bran stool marked with barium passes through the alimentary tract has been carefully

Received for publication, July 31, 1940.

†Secured from Globe-Wernicke Company.

studied,¹ but it does not seem to give better results than those based upon the weight, and a comparison of the results using weight as the criterion with results using speed as the criterion will be discussed in a subsequent report.

Bran contains approximately 8 per cent of crude fiber. Thus the usual one ounce serving of bran supplies only 2.4 Gm. of this material. This crude fiber comprises about 2 per cent of the total dry stool weight. Obviously, the bulk-forming properties of bran are not due to this small quantity of crude fiber per se.

The hydrophilic properties of bran crude fiber are negligible. Therefore, water absorption by bran crude fiber is likewise eliminated as an important factor in the formation of bulky stools.

A change in stool consistency almost always appears after the ingestion of bran: bran stools are generally softer. The change in consistency could not be accounted for by changes in moisture content, since this varied little from the control stools.

To determine moisture, about 2 Gm. of well-mixed stool were weighed on a watch glass and dried in an oven at 100° C., cooled, and weighed again; the drying and weighing were continued until the weight was constant.

In one series 7 persons (18.4 per cent) showed no change in the moisture content of bran stools. Eight persons (21 per cent) showed a decrease in moisture content, the decrease being slight (average 4.5 per cent, maximum 6 per cent). Twenty-three persons (60.6 per cent) showed an increase in moisture to a very slight degree (average 4.9 per cent, maximum 17 per cent). Bran stools definitely appeared soft, but it is impossible to distinguish between 5 per cent increase or decrease in water content by the appearance alone. While moisture may play a part in the increased softness of bran stools, the increase is not sufficiently constant to account for any substantial change in consistency. The softness is, no doubt, also due to gas. To determine whether softness is a constant change in all bran stools and to express the change quantitatively, penetrometric studies were undertaken.

PENETROMETER STUDY

The penetrometer is intended to measure the consistency of homogeneous materials. Stools are not homogeneous and, in addition, the quantity of gas which is present before expulsion of the stool from the gastrointestinal tract is no longer present. Gas is lost in transferring the specimen from the original container to the measuring apparatus and during the testing. Thus far the results of the penetrometric studies have been entirely unsatisfactory.

SPECIFIC GRAVITY OF STOOLS

Attempts to measure accurately the gas content of stools have thus far proved unsatisfactory. A considerable portion of gas is lost at defecation and during transportation, storage, and the handling of stool specimens.

Bran stools, probably due to gas content, have a lower specific gravity than control stools. It is, therefore, probable that the increase in bulk is actually greater than the increase in weight, in some cases to a considerable extent.

However, an attempt was made to develop a method for measuring the specific gravity of stools. None of the methods recommended in the literature proved satisfactory for the purpose. A liquid was required that would not dissolve or penetrate into the stool; therefore, water and similar fluids were excluded. After searching for a nonaqueous liquid and one that would not evaporate too rapidly, a petrolatum-benzin (10 per cent benzin) mixture was chosen. Approximately 5 Gm. of feces were placed in a weighed graduated centrifuge tube carefully weighed again and the petrolatum-benzin mixture was added from a burette up to the 15 c.c. mark. The weight of the specimen divided by the difference between 15 and the number of cubic centimeters of liquid added gives the specific gravity of stool.

A comparison of weight and volume in the bran and afterbran periods showed that in some cases the difference in bulk is much more obvious than that in weight. This method was abandoned because of difficulties encountered in its use.

CHEMICAL EXAMINATIONS

The pH of the stools, the total fat content, the amount of volatile fatty acids, and the relative proportion of butyric to acetic acid were determined.

Olmsted² stated that the laxative effect of bran is produced in large part by the volatile fatty acids originating from the breakdown of bran by bacteria.

Hydrogen-ion determinations (pH) were made using a quinhydrone electrode potentiometer. Solid stools were diluted two to three times with saline. In one series, the stools of 36 persons (65.4 per cent) showed a slight decrease in hydrogen-ion concentration, and those of 19 (34.6 per cent) showed a slight increase during the bran period.

The stool fat was determined by adding a quantity of 1 per cent alcoholic hydrochloric acid solution equivalent to five times the weight of the sample. This mixture was stirred well and dried on a water bath. The product obtained was extracted in a Soxhlet for twelve hours with ether. This procedure gives the total amount of nonvolatile fatty acids. During the bran period 18 per cent of 67 persons showed an increase in stool fat content, and 82 per cent showed a decrease.

Kjeldahl nitrogen determinations were made on a known quantity of dried stool. The nitrogen content of the stools was examined in the prebran, bran, and afterbran periods of some of the individuals who were on controlled diets. An increase in nitrogen was found during the bran period, probably due to a more rapid passage of the stools through the gut. The increase in nitrogen was not very marked and soon returned to normal in the afterbran period.

The volatile fatty acids in the stools were determined by releasing them from their salts by the addition of a stronger acid. About 150 c.c. of 10 per cent oxalic acid and water were added to approximately 10 Gm. of fresh stool (accurately measured) in a flask which was connected to a condenser system. The acids which passed over with the steam were taken up in a known quantity of N/5 sodium hydroxide. After the distillation was finished, the solution was titrated with N/5 sulfuric acid. The difference between the amount of alkali

in the receiving flask before distillation and the amount after distillation as indicated by the titration with N/5 sulfuric acid, gives the quantity of volatile fatty acids.

These volatile fatty acids are found to be composed chiefly of acetic and butyric acids. However, there is no correlation between an increase in stool weight and the relative proportion of acetic to butyric acid.

The amount of volatile fatty acids varied greatly in all the experiments. No uniform relationship between butyric and acetic acid was noted. Volatile fatty acids are present in the gut combined with cations, such as potassium and calcium. It must be considered doubtful whether the salts of these acids contribute to the laxative action of bran. A very careful statistical study of the question showed that the correlation between volatile fatty acids and laxative action (as measured by increased stool weight) is so slight (0.09) that it cannot be considered significant from the statistical standpoint.

CONCLUSIONS

1. The most significant change in stools following the addition of bran to an uncontrolled diet is a softening and an increase in stool weight.
2. Bran stools show an increase in bulk greater than the increase in weight. There is little variation in the percentage of water.
3. There is an increase in volatile fatty acids, chiefly acetic and butyric acids, but this increase is not proportional to the increase in weight.
4. The proportion of acetic to butyric acid showed no consistent correlation with laxative action as measured by an increase in stool weight.

We are grateful to Miss Elizabeth M. Adles for assistance in statistical studies. Protocols for all experiments are available.

LABORATORY METHODS

GENERAL

THE PRODUCTION OF ARTIFICIAL TUMORS IN THE BRAINS OF CATS*

JAMES W. WARD, PH.D., M.D., AND SAM L. CLARK, PH.D., M.D.
NASHVILLE, TENN.

THE method used in these experiments for the production of so-called artificial tumors in the brains of animals is not a new one. Rather, it is a modification of the method employed by van Schultén,¹ Hill,² and later in 1909 by Cushing and Bordley.³ Van Schultén screwed small tubes into the skulls of animals for the purpose of injecting substances into the subarachnoid space and for recording cerebrospinal fluid pressures. Hill's study of acute cerebral compression was based in part on a similar technique. His historical review of the subject is especially interesting. Cushing and Bordley used the same method in their studies, demonstrating the mechanical relationship that exists between increasing intracranial pressure and retinal edema. In some of their experiments paraffin was injected, and they noted no permanent "effect beyond that occasioned by immediate local destruction of tissue." A search of the literature has revealed no further application of this method as we have used it.

These experiments demonstrate a method whereby a foreign body, which can be increased gradually in size over a period of weeks or months, may be introduced into the brain of an unanesthetized animal and controlled in its growth. Further, they indicate some of the effects of such foreign bodies. Van Schultén's tube has been modified to resemble a grease cup, and the cups have been filled with sterile beeswax softened to a proper consistency with lipiodol. The mixture was injected slowly by turning the cup down a little each day, and has been found of itself to be relatively inert for the periods of time employed (Fig. 3). Only slight inflammation was observed in the walls around the wax. For each experiment, under aseptic conditions, a grease cup plug was screwed into a trephined hole in the skull of an animal. In all 34 cats were used. The dura under the hole was cut away before the plug was implanted and afterwards the skin was closed around it. Tubes were placed in the skulls over most of the accessible parts of the cerebral hemispheres. Records were made of the general health of the animals, and the placing reactions, described by Bard and Brooks,⁴ were tested at about daily intervals, both before and after the cups

were turned down. Observations on the optic disks, and x-ray pictures of the skulls of some of the animals were made at longer intervals. Meningitis and brain abscesses developed in several of the animals and these were discarded. With the appearance of pressure symptoms, the cats were anesthetized with nembutal, and the vascular system was injected with 10 per cent formalin. The brains were then removed for gross, and in some instances microscopic, examination.

RESULTS

It was found that the shape of the tumors could be controlled within limits by varying the relative concentration of wax and lipiodol. Mushroom-shaped masses lying under the dura were produced by the use of a mixture predominantly lipiodol (ratio 5:1). Long cylindrical masses were formed when the mixture was chiefly beeswax (Fig. 1). Spherical tumors lying below the surface of the brain were formed when a mixture of two parts of lipiodol and one of wax was used (Figs. 2 and 4).

Histologic examination of the tumors and surrounding brain tissue in sections stained with hematoxylin and eosin showed that the foreign body produced its direct effect by compression, displacement, and distortion of the normal architecture of the brain, and indirectly in some instances by blockage of the cerebrospinal fluid passages so that hydrocephalus developed. A complete fibrous capsule containing capillaries, and continuous with the dura was found around most of the tumors (Fig. 3). The pia-arachnoid appeared to be fused with this capsule at the surface of the brain where the greatest proliferation of fibrous tissue was present. A small number of leucocytes was found in the capsule, particularly on its inner surface, and some fibrin. No changes in the character or number of the supporting cells of the brain tissue itself were observed with the hematoxylin and eosin stains.

A modified Weigert's stain was applied to sections obtained from the brain of Cat 5. The rounded tumor (Fig. 2) was located just back of the motor area under the lateral gyrus on the right; it had penetrated 2 cm. downward into the brain, pushing the corpus callosum downward about 8 mm. Sections through the brain about the foreign body showed, as might be expected, a marked decreased staining capacity of the myelin sheaths of the fibers in the corpus callosum immediately under the mass. Thirty-seven days elapsed during the production of the mass, and approximately 1 c.c. of the wax mixture was injected.

In these experiments the first effect of the increasing size of the foreign body was a disturbance of the normal placing reactions. This was true no matter where the grease cups were located. However, different placing reactions in different legs were primarily affected, depending on the location of the masses. The order of appearance of deficiencies in the placing reactions resulting from wax tumors placed on different areas appears to offer some evidence as to the localization of these reactions in the cortex. On the other hand, for proper interpretation, it must be considered that transmitted pressure can be an important factor in the production of these deficiencies.

The accumulation of a mass in the middle portion of the anterior sigmoid gyrus, a region known to be a contralateral foreleg area primarily, produced first a deficiency in the abduction response in the contralateral foreleg. In another animal, pressure of the foreign body on the posterior sigmoid gyrus led to a deficiency in the contact response in the contralateral forelegs and hind-legs first. This evidence of localization is to be expected, since this region, which has been shown to be the cortical area of motor representation for these extremities (Ward and Clark⁵), has also been shown by strychninization (Dusser de Barenne⁶) to be a part of the area for sensory representation of the contralateral foreleg and to a less extent, the contralateral hindleg.

Fig. 1.—Cylindrical foreign body formed over a period of sixty-nine days (cup turned down 14 times, one turn each time). Marked hydrocephalus developed, and herniation of the cerebrum (tentorial surface) under the bony tentorium is seen at arrow.

Fig. 2.—Spherical foreign body formed over period of thirty-five days; 20 (turns) increments of wax were added. A degeneration of the myelin sheaths was noted with Weigert's stain in the corpus callosum.

Fig. 3.—Section through wall around the foreign body and the corpus callosum from cat's brain pictured in Fig. 2. Ependymal lining of lateral ventricle seen below. (See text. H. & E. Oil $\times 215$.)

In contrast to the relatively immediate deficiencies that occurred when the foreign bodies were placed in the anterior one-third of the brain, an increasing delay in the appearance of symptoms was found when the masses were more and more posteriorly placed; that is, more increments of wax (from 3 to 10 turns of the grease cup) were required before the appearance of placing reaction deficiency.

Fig. 4.—X-ray pictures of spherical foreign body formed in nineteen days (15 turns).

In 8 cats with masses on the posterior two-thirds of the cerebrum, the first alteration of the normal activity was noted to be a slowing in the contact reaction in the contralateral hindleg. Bard and Brooks have shown the integrity of the placing reactions to be dependent on the area immediately around the cruciate sulcus and the most anterior end of the lateral gyrus. The results of experiments in which the masses were located in various parts of the posterior two-thirds of the cerebrum demonstrate the effect of the pressure exerted either on a "center," or on nerve pathways leading to or from such a "center." It does not appear likely that the cortical "centers" subserving the placing reactions are those affected by the pressure of these remote masses, because when pressure is exerted directly against these regions, either different placing reactions or combinations of placing reactions are affected first. A selective effect of pressure transmitted downward to the centrifugal or centripetal cortical pathways appears to offer a more likely explanation. Whether this is due to a selective loss of function like that which occurs with pressure on a peripheral nerve (Gasser and Erlanger⁷), or whether it is the result of pressure on the blood vessels supplying these regions is not known.

Remissions of symptoms frequently occurred when more than twenty-four hours elapsed between successive additions of wax. This is illustrated in an animal (Cat 19) with the grease eup on about the middle of the right lateral gyrus close to the midline. The eup was turned down one turn each day for the first seven days. The contact placing reactions after the first forty-eight hours became progressively slower and smaller in both hindlegs. The responses of the forelegs remained normal. No increment was added on the eighth day, and within the next twenty-four hours all reactions became normal. The contact response in the hindlegs again was slightly reduced on the eleventh day after the additions of wax were resumed on the ninth and tenth days. X-ray pictures of the skull showed that the mass occupied a position on both sides of the midline in the posterior one-third of the cerebral cranial cavity (Fig. 4).

The location of the masses in the cranial cavity appeared definitely related to the time of appearance and intensity of the symptoms of compression. The slowly enlarging foreign bodies produced displacement of the brain tissue, and in some instances this displacement was enhanced by the additional factor of hydrocephalus, the hydrocephalus being caused by the indirect blockage of the drainage passages of the cerebrospinal fluid by the foreign bodies. Autopsy revealed the presence of pressure cones in the animals that survived for several weeks or more, though dilated ventricles were present only in some of these. In those with undilated ventricles the tumors were frequently large and usually situated so as to produce most of their displacement from the front of the cranial cavity. When situated more posteriorly, tumors formed by slower and less frequently added increments of wax tended not to be associated with dilated ventricles, even though tumors similarly situated did lead to distended ventricles if they were formed more rapidly. In all probability the factor of rate of growth accounts for the lack of early symptoms in certain human cases in which enormous, slow-growing tumors have eventually manifest themselves.

As the wax masses were increased in size, the effects on the animals presented a fairly constant pattern. A blurring of the edges of the optic disks with engorgement of the veins was seen. The cats sat very quietly, back humped, nose down, neck extended, feet bunched. When they were handled, they were found to be tense and at times cried angrily and lashed their tails. They were usually unsteady on their feet, and the placing and hopping reactions were lost in all legs. They appeared to prefer to lie on the side opposite the mass if the mass was definitely asymmetrical in its position. The pupils were usually dilated and responded to light slightly, or not at all; and vision appeared to be impaired in that the animals often ran into objects as they moved about.

Terminally the animals exhibited some of the symptoms characteristic of decerebrate rigidity. They were no longer able to stand, and their heads and necks were thrown back. While the cats were lying undisturbed, their forelegs were extended and retracted, and their hindlegs were partially flexed. The Stutz reaction was easily elicited in the forelegs. Local reflex activity was unimpaired. Slow running movements occurred at times in the course of this stage. Death followed shortly. For example, in Cat 34 the mass was located close to the midline and in the middle third of the cerebrum and had been produced rapidly (16 turns, 2 each day). Death occurred on the eighth day, though no symptoms appeared until the seventh day. Autopsy showed slightly dilated ventricles, a cerebral herniation at the tentorium and a cerebellar pressure cone at the foramen magnum. A bony tentorium cerebelli in the cat is probably responsible for some of the symptoms of decerebration that are to be observed in these acute stages. Compression of the brain stem under the tentorium occurs with the herniation of the pulvinar and the tentorial surface of the cerebrum. This herniation was observed in all animals allowed to go to this advanced stage (Fig. 1).

SUMMARY AND CONCLUSIONS

The experiments demonstrate a method whereby foreign bodies that simulate growing benign tumors can be placed on various parts of the brains of animals.

The masses give rise to localizing symptoms, and a chronic state with evidence of increased intracranial pressure can be produced.

An acute state of increased intracranial pressure may develop with rapid injection of the wax mixture; hydrocephalus may develop and become a factor in the production of the symptoms. Some symptoms of decerebration characterize this state.

The masses can be visualized in the living animal by x-ray pictures.

The experiments indicate in another way that parts of the motor area in the cat subserve certain placing reactions in different extremities. Of these placing reactions it was found that the contact reaction was the most labile in that pressure exerted on parts of the cerebrum other than the motor region caused an elimination of this reaction before abolishing the others.

A METHOD FOR PREPARING SMEARS AND SECTIONS OF ASPIRATED STERNAL MARROW*

HAROLD GORDON, M.S., M.D., LOUISVILLE, KY.

THE diagnostic value of biopsies of sternal marrow is so firmly established that the time may soon arrive when failure to examine the marrow of a patient with an obscure hematologic disorder will have medicolegal significance. Many instruments have been devised, and several methods have been suggested to facilitate the procedure of sternal biopsy. These fall into two general categories: aspiration and trepanation techniques. The latter possesses a number of advantages as pointed out by Custer,¹⁻³ Dameshek, Henstell, and Valentine,⁴ and Hynes.⁵ It also has important limitations, as emphasized by Young and Osgood.⁶ Some workers have devised instruments by means of which solid fragments of spongy bone may be removed from the sternum by a modified trephine technique.^{7, 8} However, all the various trepanation methods have the serious disadvantage of being relatively formidable procedures which cannot be repeated at short intervals. The advantages of the aspiration technique are so many that it is the method of choice of most clinicians. It has one serious drawback—the lack of organized tissue makes impossible a well-oriented study of tissue relationships. In order to overcome this difficulty, it has been suggested⁹⁻¹¹ that smears may be made of some of the marrow and the remainder be allowed to clot. The clot may then be fixed, embedded in celloidin or paraffin, sectioned and stained. Reich,¹² and Vogel, Erf, and Rosenthal¹³ concentrated the marrow by centrifuging it and made smears from the buffy coat. The method described below is a further modification of the foregoing and permits the making of smears from sternal marrow both before and after concentration by centrifuging, as well as the preparation of tissue sections. It requires no special instruments, avoids excessive hemodilution, and yields material which is adequate for diagnosis in almost every instance.

METHOD

An 18 gauge spinal puncture needle is filed through $1\frac{1}{2}$ inches from its shaft, its point is rebeveled, and a fine mark, 0.6 cm. from the tip, is made on it with a file. The purpose of this mark is to provide a convenient guide whereby the operator may judge the depth of penetration of the needle when in use. The usual thickness of the outer table of the sternum is 0.4 cm.; hence, when the file mark is flush with the skin, the point of the needle is usually within the marrow cavity. The puncture site, preferably in the midline between the second and third ribs, is cleansed with iodine and alcohol and infiltrated with novocain solution. The novocain should be injected into the skin, subcutaneous tissues, and periosteum. The puncture needle, with stilet in place, is pushed through the soft tissues and into the outer table of the sternum. The operator should hold the needle in such a way that the file mark is grasped firmly between his thumb and index finger, while the broad base of the needle fits snugly into the palm of his hand. This enables him to push the needle into the marrow cavity without losing control of the instrument.

Penetration of the cortex of the bone is facilitated by rotating the needle slowly as it is pushed in with a steady pressure. When the file mark is flush with the skin, the stilet is withdrawn, and a 5 or 10 c.c. syringe is fitted to the needle. Trial aspiration is made by applying negative pressure to the syringe. Usually marrow mixed with blood is obtained at the first trial. Sometimes it is necessary to remove the syringe, replace the stilet, and go a little deeper in order to obtain marrow. This happens especially if the patient is obese, or if the skin is edematous. Experience soon permits the operator to gauge the thickness of the subcutaneous panniculus while he is infiltrating the tissues with novocain. If, in his judgment, the soft tissues are unusually abundant, he may hold his thumb and index finger "stop" a corresponding distance above the file mark, which is based upon the average thickness of the soft tissues and the outer table of the sternum. The sternal marrow should be withdrawn rapidly, using strong negative pressure. This occasions a moderate feeling of discomfort but aids in dislodging minute plugs of marrow. It is not advisable to withdraw more than 1.0 c.c. of marrow in order to minimize hemodilution. As soon as the syringe is filled to the 1.0 c.c. mark, the needle and syringe should be withdrawn, and their contents emptied into a small test tube containing sufficient dry oxalate to prevent clotting. Pressure is then applied to the sternal puncture site and a sterile dressing is affixed.

Smears are made immediately from the "oxalated" marrow, dried in air, and stained with Wright's stain. The undiluted stain is allowed to act for two minutes, care being taken to avoid evaporation and precipitation of the stain. If some of the stain becomes precipitated, an additional drop or two will dissolve the precipitate. The stain is diluted with distilled water and allowed to remain on the slide for six to eight minutes longer. The stain is washed off with distilled water and the smears may be examined immediately, using the low-power objective to ascertain whether or not they are satisfactory for diagnostic purposes. If the smears are considered satisfactory, the remainder of the marrow is centrifuged at low speed for fifteen to twenty minutes. The

clear supernatant fluid is pipetted off, and additional smears are made from the concentrated buffy layer. These are stained with Wright's stain as previously. The remainder of the marrow is removed gently from the tube and placed on a small piece of dry filter paper, to which it will adhere firmly. The filter paper with adherent marrow is placed in 10 per cent aqueous solution of formalin, dehydrated in alcohol, cleared in xylol, embedded in paraffin, and sectioned. The sections should be from 4 to 6 microns thick, and several duplicate sections

Fig. 1.—A fragment of aspirated sternal marrow. Hematoxylin and eosin stain. Magnification 190 diameters (approximately). The marrow was removed from a white male, aged 22 years. Although the marrow was hypoplastic (confirmed at necropsy), two small fragments of organized marrow tissue were obtained. Both showed a marked granulocytopenia, a moderate decrease of erythropoiesis, and a diffuse fatty replacement of the marrow.

may be mounted on each of two slides. They may be stained with hematoxylin and eosin or with methylene blue, eosin-phloxin.¹⁴ Small fragments of marrow will usually be present in the sections. These frequently appear as well-organized pieces of tissue, even in a marrow which is hypoplastic (Fig. 1). In leucemic marrow, groups of atypical cells often are collected in nests about small vessels (Fig. 2). Occasionally no organized tissue is found in the sections, and sometimes the centrifuged material disintegrates as it is sectioned. However, during the three-year period the method has been in use, very few such failures have been encountered. Moreover, in the occasional case in which no tissue frag-

ments are found, the smears still are available for examination. One other point is worthy of emphasis: in no instance has sternal puncture caused local implantation metastases in my experience and no instance of such a sequel can be found in the available literature. This is of considerable practical importance and is very remarkable in view of the fact that thousands of sternal punctures have been performed during the past few years. It is all the more significant when it is considered that many of these punctures revealed the presence of a variety of malignant neoplasms in the sternal marrow.

Fig. 2.—Sternal marrow obtained by aspiration. Hematoxylin and eosin stain. Magnification 190 diameters (approximately). The marrow was aspirated from a patient with diffuse plasma cell myelosis. Note the small vessel in the center and the groups of plasma cells in the adjacent perivascular spaces.

SUMMARY

A method is described whereby sternal marrow may be obtained by aspiration and prepared in the form of both smears and tissue sections.

Attention is directed to the fact that no examples of implantation metastases have been encountered following aspiration of sternal marrow.

ISOPROPYL ALCOHOL AS A DEHYDRATING AGENT AND PRESERVATIVE FOR BIOLOGICAL SPECIMENS*

CARLTON M. HERMAN, SC.D., SAN DIEGO, CALIF.

DURING recent years isopropyl alcohol has been coming into wider use as an antiseptic and sterilizing agent, but little emphasis has been placed on its applicability to general biological routine processes in the laboratory. Its use in the latter connection was first pointed out by Griffin.¹ Isopropyl alcohol, C_3H_7OH , is an inexpensive by-product of the oil industry, with properties very similar to ethyl alcohol. It costs less than tax-free 95 per cent ethyl alcohol. It is not palatable as a beverage and is not subject to the extensive bonds and responsibilities required in the use of tax-free ethyl alcohol. It is a water clear liquid, completely miscible with distilled water. It is sold commercially as anhydrous isopropyl alcohol, with less than 1 per cent of water and other impurities, and as such acts as well as absolute ethyl alcohol in dehydrating procedures. In the preparation of histologic and pathologic material, it is the equal of ethyl alcohol as a dehydrating agent, preservative, and solvent for stains. We have used it extensively in the staining procedure for the diagnosis of parasitic protozoa in fecal smears with excellent results. In fact, we have entirely replaced it for ethyl alcohol for all purposes in our laboratory.

A PRACTICAL METHOD FOR INTRASTATE EVALUATION OF THE PERFORMANCE OF SEROLOGIC TESTS FOR SYPHILIS*

S. R. DAMON, PH.D., AND C. BROUGHIER, B.S.
MONTGOMERY, ALA.

INTRODUCTION

THE improvement of laboratory tests used as aids in the diagnosis of disease is a matter of fundamental importance, not only to the medical profession but also to the public as well. Refinements in technique and new discoveries have added much in accuracy in recent years to many laboratory tests; however, constant vigilance must be exercised to insure that new procedures do not sacrifice too much in specificity in the effort to attain speed and sensitivity.

In those states where the State Department of Health maintains a Bureau of Laboratories, consisting of a central laboratory and several branch laboratories, and in those states where private clinical laboratories are officially authorized to perform certain kinds of examinations, under supervision of the State Board of Health, some means of checking performance is essential. This is true particularly where laws are in effect requiring certification of freedom from venereal disease, based on physical examination and certain laboratory tests, before marriage licenses may be obtained. Usually these tests consist of serologic tests for syphilis, and, where indicated, microscopic examinations of smears for evidence of gonorrhea. It is true, of course, that while the results of these laboratory tests per se are not sufficient grounds for denial of a license, the actual tests performed should, nevertheless, be of the highest degree of reliability, i.e., they should be above question as to their sensitivity and specificity.

A survey of the literature relating to the serodiagnosis of syphilis is likely to leave one confused due to the multiplicity of tests from which to choose. It should be remembered, however, that in the last analysis the value of any technique depends, first, on its specificity, that is, its failure to give positive reactions in conditions other than syphilis; and second, on its sensitivity, that is, the proportion of actually syphilitic patients detected by the test. The very multiplicity of available procedures, and the conflicting claims made for them, is sufficient indication that the perfect test has not yet been devised. The most practical way of evaluating this or that particular technique is, therefore, by properly controlled comparisons on parallel series of specimens.

SEROLOGIC CONFERENCES

Within recent years several official attempts have been made to evaluate the merits of various complement fixation and flocculation procedures. In the first place conferences were conducted by the health organization of the League of Nations in 1923, and 1928, and 1930, at which duplicate samples of some hun-

*From the Alabama State Department of Public Health, Montgomery.
Received for publication, September 11, 1940.

dreds of sera were tested by the serologists who had devised diagnostic tests for syphilis, each serologist performing his own test.

Subsequently, the first attempt in the United States at determining the relative values of various techniques was made in 1934-1935, under the joint auspices of the United States Public Health Service and the American Society of Clinical Pathologists. Still later, another evaluation study was carried out in 1937, and others followed in 1938, 1939, and 1940, the scope of participation having been broadened to include not only laboratories of the originators of tests but also most state laboratories and some municipal laboratories as well.

As a result of these comparative studies it has been shown that there are at least five serodiagnostic tests for syphilis which are satisfactory in both sensitivity and specificity as long as the technique of the originator is strictly adhered to. However, the studies also showed that marked variations were obtained by laboratories using supposedly the same procedure when the directions for performance given by the originator of a test were not strictly followed.

As an outgrowth of these evaluation studies, critical reviews of procedures have been stimulated, with the result that substandard or obsolete techniques have been abandoned and emphasis has been placed on the importance of strict adherence to all the minor technical details of a described procedure. The net result has been a marked improvement in the sensitivity and specificity of the serodiagnostic tests for syphilis routinely carried out in the participating laboratories.

THE PROBLEM IN ALABAMA

For many years the Bureau of Laboratories of the Alabama State Board of Health has attempted to attain uniformity of procedure in its central and branch laboratories by various means, including the use of check specimens. Efforts have also been made along this line in cooperation with hospital and private clinical laboratories within the state.

Check specimens for the evaluation of serologic tests for syphilis have been somewhat of a problem, however, since completely authenticated specimens from known syphilitic and nonsyphilitic persons, in numbers necessary for adequate evaluation, such as have been furnished in the interstate evaluations of the United States Public Health Service and the intrastate evaluations conducted in Maryland¹ in 1939-1940, and in Georgia² in 1940, have not been available. As a substitute for such specimens, and as a means of making possible continuous weekly checks of serodiagnostic tests for syphilis, the following procedure has, therefore, been used for some time in Alabama.

METHOD

The primary assumption of this method of evaluation is that certain serodiagnostic tests for syphilis have already been demonstrated to be satisfactory by the United States Public Health Service. Consequently, evaluation of the ability of a procedure to detect diminishing amounts of reagin in diluted specimens constitutes an adequate check on the sensitivity of the test in the laboratory being checked. Sufficient negative sera are included over a period of time to evaluate specificity.

Blood specimens received in the central laboratory for serologic test for syphilis are first tested routinely by means of the presumptive Kahn test. Sera that give a negative result by this test, which are to be used in the preparation of check specimens, are set aside and later retested by the presumptive Kahn test, using the serum undiluted and in a 1:5 saline dilution, to assure against technical errors and prozones. Sera reacting negatively to these two tests are pooled for use in preparing check specimens. Diagnostic sera giving any degree of reaction in the presumptive Kahn test are subjected to the standard Kahn test; sera giving a strongly positive reaction with the standard Kahn test are also pooled for use in preparing check specimens. The pooled negative sera and the pooled positive sera are Seitz-filtered separately, to free them from bacteria and undesirable precipitates; such filtration has caused no difference in reactivity so far as parallel specimens have indicated.

Eight dilutions of positive in negative serum—1:2, 1:4, 1:5, 1:8, 1:10, 1:16, 1:20, and 1:30—are prepared in sterile flasks. These dilutions are most easily prepared by making basic dilutions of 1:2 and 1:5, and preparing the higher dilutions from these. These dilutions are transferred to sterile, corked tubes, serially numbered in groups of 10; the numbers on the tubes purposely bear no relationship to the dilution of serum; the ninth and tenth tube in each group are for the inclusion of one tube of undiluted positive serum and one tube of undiluted negative serum. Approximately 200 c.c. of negative serum and 50 c.c. of positive serum have been found ample for preparing the 10 check specimens for 12 to 15 laboratories. Sets of tubes are assembled, and a sheet of instructions as to the inactivation and the method of reporting results is included, and the specimens are mailed to the various laboratories simultaneously. When the results are received, they are tabulated as shown in Table I; errors are checked and a copy of the composite results is sent to each serologist.

INTERPRETATION OF REPORTED RESULTS

From Tables I and II it appears that any laboratory which obtained a 2+ or stronger reaction in its diagnostic test with these particular sera in a 1:5 dilution was running a satisfactorily sensitive test, and for that reason a line is drawn across the tables after the 1:5 dilution. Any laboratory which failed to get a positive reaction in this dilution was considered as conducting an insensitive test. If any error is made in the choice of this critical dilution, it is believed that it is on the side of conservatism, since it is thought that an effort to obtain maximum sensitivity may result in a certain number of false positives, i.e., some loss in specificity.

In Table I it appears that laboratories 1 and 2 underread or overread the sera diluted 1:16 and 1:20, and that laboratories 2 and 6 performed supersensitive presumptive Kahn tests. It also appears that laboratory 7 underread the 1:4 or overread the 1:5 dilutions of its standard Kahn test, whereas laboratory 9 performed an undersensitive presumptive Kahn test.

In Table II, on the particular day these specimens were examined, laboratories 13, 14, and 15 conducted undersensitive complement fixation tests, and laboratory 13 an undersensitive standard Kahn test. In laboratory 12

underreading in the lower dilution or overreading in the higher dilution seems to have occurred in the 1:8 or the 1:10 dilution in the presumptive Kahn test, and in the 1:16 or the 1:20 dilution in the standard Kahn test. The same error seems to have been made in laboratory 14 in the 1:4 and 1:5 dilutions in the Wassermann test. In laboratory 10 a certain degree of false positive reaction was obtained in the negative control serum with an Eagle flocculation test.

SUMMARY

A plan is presented for the conduct of serologic check testing which is being used with success by the Bureau of Laboratories of the Alabama State Department of Public Health. The plan has several important advantages. It is inexpensive. It utilizes materials available in the laboratory every day. It enables checking of performance at weekly intervals throughout the year. By including enough frankly negative sera with those that contain varying amounts of reagin, it checks on both specificity and sensitivity. It readily indicates errors in technique, and it encourages revisions in procedure.

CONCLUSIONS

1. Intrastate evaluations of the performance of serologic tests for syphilis are of great value, not only to the participating laboratories but also to the physicians and to the public.

2. To be of greatest usefulness the evaluation of performance of serodiagnostic tests for syphilis must be made at frequent intervals.

3. A practical method for conducting intrastate evaluations of serologic tests for syphilis, based on the "horizontal method of analysis," has been described.

4. The method described is economical and checks both specificity and sensitivity.

5. On the basis of check testing by the method described, provision is made to assist any laboratory in improving its performance of serodiagnostic tests for syphilis through inspection, and the instruction of serologists in the Bureau of Laboratories of the State Department of Health.

A SIMPLE MODIFICATION OF WELTMANN'S COAGULATION REACTION*

DAVID H. KLING, M.D., LOS ANGELES, CALIF.

NUMEROUS investigators abroad, and Kraemer,¹ Levinson, Klein, and Rosenblum^{2, 3} in this country, have established the value of Weltmann's serum coagulation reaction for diagnosis and prognosis. However, the original technique is too cumbersome to be used as routine procedure. It involves the frequent preparation of ten solutions of calcium chloride, a set-up of at least ten test tubes, and a water bath. The modification outlined here requires only one test tube, one standard solution of calcium chloride, and 0.1 ml. of serum.

TABLE I

	TUBE I	II	III	IV	V	VI	VII	VIII	IX	X
Weltmann's method										
CaCl ₂ /1,000	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
mg. CaCl ₂ /5 ml.	5.0	4.5	4.0	3.5	3.0	2.5	2.0	1.5	1.0	0.5
Modification										
ml. of 1% CaCl ₂	0.5	0.45	0.4	0.35	0.3	0.25	0.2	0.15	0.1	0.05
			Exudative zone			Normal zone			Fibrotic zone	
			Shift to left						Shift to right	
			Short band						Long band	

Principle.—A 1:50 dilution of normal human serum with distilled water does not coagulate on heating unless a bivalent electrolyte, such as calcium chloride, is added to make a concentration of 0.4 to 0.5 per thousand. Sera from conditions where exudation prevails, such as pneumonia, acute rheumatic fever, and exudative tuberculosis, require an increased concentration of electrolyte to one per thousand and more. On the other hand, sera from cases where fibrosis and liver damage are prominent, such as fibrotic tuberculosis, subacute atrophy of the liver, cirrhosis of the liver, and septic conditions, coagulate with very low concentrations (0.1 to 0.3 per thousand).

Weltmann placed into ten test tubes 4.9 ml. of solutions, ranging from one per thousand to 0.1 per thousand of crystalline calcium chloride. The integral amounts to 0.1 per thousand or 0.5 mg. calcium chloride per 5 ml. This amount is contained in 0.05 ml. of a 1 per cent solution of calcium chloride, which is the standard solution used in the modification.

Technique.—Into a medium-sized test tube (about 6 by 0.5 inches) place 4.9 ml. of distilled water and 0.1 ml. of clear nonhemolytic serum. Add from a 0.1 ml. pipette 0.05 ml. of 1 per cent calcium chloride (equal to 0.5 mg.). Shake and bring to a boil over a small flame. Cool and repeat the procedure until flocculation has taken place. Note the milligrams necessary to produce floccula-

Received for publication, September 13, 1940.

tion. Table I gives the conversion into the corresponding calcium chloride concentration and also for comparative purposes the number of the tube of Weltmann's original reaction. Violent boiling should be avoided because it may lead to foaming and loss of fluid. The observation for flocculation should be made after cooling. In practice it is not necessary to proceed by single units of 0.05 ml.

The first boiling can be done after the addition of 0.15 ml. of calcium chloride. This is still lower than the concentration necessary for the flocculation of normal serum and is characteristic of fibrotic processes. If the serum is from known exudative cases, such as pneumonia or active tuberculosis, the test can be started by the addition of 0.25 ml., the upper normal range. After one has acquired enough experience, he can judge by the amount of turbidity after the first boiling approximately how many more units of calcium chloride will still be required, thus shortening the test.

A slight increase in dilution of serum occurs by the addition of calcium chloride to the 1:50 dilution. For the whole range of the Weltmann test the error is not greater than 1 to 10 per cent, which is compensated by the loss of fluid through boiling. A comparison between the original Weltmann test and the modification in 61 cases showed an average difference of less than one tube. In severe exudative cases, such as pneumonia, where flocculation may occur far beyond the range of 1:1,000 (Weltmann's tube I) 15 to 20 tubes would have to be set up. By the modification the severest stages are conveniently and quantitatively determined by the simple addition of the number of units of the calcium chloride necessary for complete flocculation. The results of the test in 307 cases are summarized in Table II.

TABLE II

CONDITION	NUMBER OF CASES	MAXIMUM	MINIMUM (ML. OF 1% CaCl_2)	AVERAGE
Pneumonia	31	1.0	0.3	0.59
Bronchitis, influenza	6	0.45	0.2	0.35
Pulmonary tuberculosis	29	0.65	0.15	0.36
Tonsillitis	14	0.45	0.2	0.26
Inflammation of gall bladder, urinary bladder, sinuses, prostate	34	0.55	0.15	0.3
Fibroid tumors	5	0.5	0.2	0.35
Carcinoma	7	0.5	0.15	0.26
Pregnancy, post partum	32	0.45	0.15	0.25
Arteriosclerosis, hypertension, chronic myocarditis and circulatory disorders	23	0.7	0.2	0.25
Appendicitis	16	0.65	0.15	0.28
Chronic gonorrhea	5	0.55	0.2	0.32
Syphilis	9	0.4	0.2	0.28
Goiter	7	0.3	0.15	0.27
Gout	6	0.35	0.3	0.33
Infectious, rheumatoid arthritis	48	0.55	0.15	0.36
Osteo-arthritis	35	0.45	0.15	0.27

The cases were not selected as to stage or complications. The maximum values indicate the degree of exudation which is brought about primarily either by the disease, such as pneumonia or active tuberculosis, or by the secondary tissue destruction and inflammation, such as occur in carcinoma. The minimum

values are characteristic for subsidence of exudation, development of fibrosis, or a combination of both processes in the chronic stages.

Of the modifications which have been published abroad, Havas' micromethod retains the cumbersome original technique. The only advantage is reduction of the necessary reagents and serum to one-tenth of that required by the Weltmann method. Tenfel's modification uses the same principle as described in this paper, but employs only 0.5 per cent calcium chloride. The error of dilution is, therefore, doubled. To deliver the calcium chloride he uses special droppers which are expensive, not easily available, and introduce another error because they do not deliver the exact unit of calcium chloride that is required.

I wish to express my appreciation to Dr. Orlin B. Pratt, director of the laboratories, Department of Pathology, White Memorial Hospital, College of Medical Evangelists, for providing the facilities of the laboratory for this work.

NITRIC AND SULFURIC ACIDS. A COLORLESS CLEANING MIXTURE FOR GLASSWARE

WALTER C. TOBIE, PH.D., OLD GREENWICH, CONN.

MANY scientific workers are apparently unaware of the useful properties of a mixture of nitric and sulfuric acids for cleaning glassware.

The most commonly used cleaning mixture consists of concentrated sulfuric acid containing dissolved sodium or potassium dichromate (or better, chromium trioxide). When freshly prepared, this makes an excellent cleaning solution, but it rapidly becomes spent with use, turning green owing to the reduction of the chromium trioxide by organic materials on the glassware. More of the chromium compound may then be added, but the mixture soon becomes so thick and pasty that it must be discarded. This mixture has the further disadvantage of having a very dark color, so that it is extremely difficult to find small objects and to remove them from the bath. Furthermore, it is claimed¹ that traces of chromium which adhere to the glass can only be removed by very extensive washing, and, therefore, may contaminate biological materials which subsequently come in contact with the glass. This is especially true in the case of fritted glass filters. Traces of chromium have a strongly toxic action on many microorganisms.²

A mixture of concentrated sulfuric and nitric acids has none of these disadvantages. A cold mixture containing about 10 per cent of nitric acid by vol-

ume is very effective in removing traces of grease from glassware (such as pipettes or microscope slides) after a few hours' immersion. When hot, the mixture is extremely effective in oxidizing large amounts of organic material (such as resins, oils, or dried biological fluids) adhering to the glass. In so doing, it often takes on a brown color due to partly oxidized organic matter and liberated nitric oxide, but upon continued heating to complete oxidation, the color of the bath will return to light yellow or light yellow green. Too much organic matter will consume the nitric acid, in which case more can be added as needed. It should be stirred in well, preferably after the mixture has cooled.

If much cleaning is done a convenient method of use is to maintain a bath of sulfuric acid in a large evaporating dish or other acid-resisting container on a gas range or electric hot plate under a hood, and to add a small amount of nitric acid with thorough stirring at the beginning of each day's work, before turning on the heat. A duriron dish is extremely desirable, and avoids the danger of breakage which is always present with porcelain or glass containers. The nitric acid should be well stirred into the cold sulfuric acid, otherwise it will form a layer on the surface and will evaporate rapidly as the bath becomes hot. Such a cleaning bath may be maintained for several months, and need only be discarded when the sulfuric acid has become viscid by the slow accumulation of inorganic salts from the oxidized materials.

The mixture has the disadvantage of fuming somewhat when exposed to the air, especially when heated; hence to avoid breathing the irritating fumes it should be used in a hood with a good current of air. As with the dichromate-sulfuric acid mixture, great care should be taken to avoid splashing the mixture on the hands or clothing, since severe burns may result. Steel crucible tongs are useful in removing glassware from the bath, and such glassware should be well cooled under the hood before rinsing with water. If exposed to the air for several days without heating, the mixture will absorb atmospheric moisture and increase in volume, but the absorbed water rapidly evaporates when the bath is heated again.

The use of chlorates or perchlorates in sulfuric acid cleaning baths has sometimes been proposed, but such mixtures are *extremely dangerous* on account of the explosion hazard and should always be avoided. Sodium or potassium nitrates have also been used, but they have no advantages over nitric acid. The addition of any solid salt will make the bath viscid and shorten its useful life.

Care should, of course, be taken not to heat the mixture so hot that white fumes of sulfuric acid arise, since this will cause a large loss of the acid. If enough nitric acid is present, very gentle heating is usually sufficient to oxidize most organic materials on the glass.

FREEZING OF TISSUES WITH "DRY ICE" FOR MICROTOME SECTIONING OF THE ENTIRE BRAIN*

THEODORE S. ROSEN, M.D., AND GEORGE W. LUBINSKY, A.B.
NEW YORK, N. Y.

IN RECENT YEARS, solid carbon dioxide ("dry ice") has been used in freezing tissues preparatory to sectioning and has been found to have many advantages over the gas. Lindsay and co-workers,¹ and Dunn² described "dry ice" attachments for freezing small blocks of tissue, which can be used with the standard freezing microtome. Mason³ devised a method of using the rocking microtome for sections frozen with carbon dioxide gas.

We have constructed a "dry ice" attachment by which coronal sections of the entire cerebrum may be easily frozen and cut on the larger sledge type celloidin microtome (Minot-MacCallum). For those laboratories which possess a microtome that can accommodate sections 4 by 4 inches (Minot), a smaller attachment was constructed. With this attachment, a coronal section of one cerebral hemisphere, the basal ganglia, whole animal brains, infant brains, kidneys, spleens, etc., may be sectioned.

FREEZING APPARATUS

The freezing attachment consists essentially of (1) a metal plate upon which the slab of tissue is frozen, and (2) a means of keeping the "ice" which in turn chills the tissue, at the same time anchoring the tissue to the plate. Freezing will not occur unless the "ice" is in contact with the plate. After the "ice" is removed, the hardening process continues from the cold plate. With a thin plate, the freezing process is rapid; a thicker plate slows the freezing process but retains the cold longer.

The freezing plate of the larger apparatus consists of sheet aluminum, $\frac{1}{8}$ inch thick and measuring $6\frac{1}{2}$ by 5 inches. This is screwed to a bakelite box,† measuring $6\frac{1}{16}$ by $5\frac{5}{16}$ by $2\frac{5}{16}$ inches, of which it becomes the roof. The end of the box is cut away, and a wooden drawer is built to fit snugly into the box through this end. The drawer (Fig. 1, *D*) contains a slab of "dry ice" (*I*) which is forced against the aluminum plate (*P*) by a false bottom (*F*) mounted on spiral springs (*S*). The springs slide on thin metal tubes (*T*), each of which surrounds a bolt (*B*) which is fastened to the floor of the drawer by a nut (*N*). At the free end of the bolt, a washer (*K*) and nut (*M*) limit the upper excursion of the false bottom. The washer (*W*) helps keep the spring in place. The bakelite box (*X*) is screwed to the object clamp supporting base of the microtome.

Received for publication, September 13, 1940

†Molded Bakelite Meter Box, No. K10531, sold by the Lafayette Radio Company, 100 6th Avenue, New York City.

To anchor the tissue more firmly to the freezing plate, moistened filter paper may be interposed, or deep grooves may be cut into the plate.

The smaller apparatus consists simply of an electrical conduit box, 4 by 4 by $1\frac{5}{8}$ inches, and a false bottom of hard rubber mounted on springs, as in the

Fig. 1.—Diagram of freezing attachment. See text for explanation of letters.

Fig. 2.—Top view of larger freezing attachment, showing aluminum freezing plate and partly open drawer containing a slab of "dry ice."

larger apparatus. The cover of the box is used as the freezing plate. No drawer is used in this case. When the tissue is frozen, the freezing plate is slipped off and the "ice" is removed. The plate is then screwed in place, the box is placed in the object clamp of the microtome, and cutting can begin.

Fig. 3.—Side view of larger freezing attachment, showing bakelite box attached to object clamp supporting base of microtome.

Fig. 4.—Top view of smaller freezing attachment, showing partly removed freezing plate and false bottom within conduit box.

TECHNIQUE

The brain is fixed for ten days in 10 per cent formalin and then cut into slices 1 cm. thick. A slab of brain is placed on the freezing plate and "dry ice" is placed in the freezing chamber. A glass dish is inverted over the tissue. The freezing process varies according to room temperature. Ordinarily the "ice" is removed in about five minutes. The hardening process continues for a few minutes after the "ice" is removed. The surface of the section should be blotted free of water to prevent the formation of ice. Sections 20 to 30 microns thick may be obtained. The sections are brushed into a pan of water where they are straightened out without difficulty. They are easily transferred from dish to dish during the staining process by means of a large perforated flat spoon previously described by Lubinsky.⁴ Further technical details are well outlined in Christeller's *Atlas*⁵ and may be found in Abbott's translation.⁶

ADVANTAGES OF "DRY ICE" METHOD

1. The attachment for freezing coronal sections of the entire cerebrum can be made with materials costing less than \$2.00. The smaller attachment costs about 30 cents. This is a small fraction of the price for a large carbon dioxide gas attachment. No special microtome is required. Using the principles described, one may devise an attachment to suit any microtome.

2. When carbon dioxide gas is used for freezing coronal sections of the cerebrum, a large tank is soon exhausted. "Dry ice" costs only a few cents a pound. A pound of "ice" can be used for freezing two or more coronal sections.

3. The freezing process with "dry ice" requires about five minutes and sectioning may proceed for ten to fifteen minutes. Because of this long interval, some serial sections may be obtained and little tissue is lost in preparatory cutting. According to Christeller, the freezing process with carbon dioxide gas requires twenty to thirty minutes for large sections, and with this method only a few minutes are available for sectioning before refreezing is necessary.

4. The attachment requires little space and is easily transported.

We wish to acknowledge our indebtedness to Dr. Tracy Putnam at whose suggestion this work was undertaken.

AN EFFICIENT OXYGENATOR FOR BLOOD*

JOHN H. GIBBON, JR., M.D., AND CHARLES W. KRAUL, A.B.
PHILADELPHIA, PA.

IN AN EARLIER publication¹ a method of introducing oxygen into blood was described. It consisted of producing a thin film of blood on the inner surface of a vertical revolving cylinder. The apparatus was not capable of introducing oxygen rapidly enough for the experimental purposes for which it was designed. In the present report a larger cylinder of improved design, capable of introducing 60 per cent more oxygen into blood, is described.

The principal feature of the apparatus is a vertical steel cylinder, 24 inches in length and $8\frac{1}{2}$ inches in inside diameter (Fig. 1). The cylinder is supported by two sets of roller bearings with circular racers. These allow the cylinder to revolve around a vertical axis. The racers are in turn supported by a vertical steel pipe 4 inches in diameter, with a wall $\frac{5}{8}$ inch thick. The pipe is 40 inches high, mounted on a steel base, 12 by 20 inches in area. Revolution of the cylinder is accomplished by a one-quarter horse power A.C. motor, attached by a pulley and V-belt to a vertical segment of a steel sphere covered with hard rubber (Fig. 1, side view). The convex surface of the segment of a sphere is pressed by a strong steel spring against the beveled edge of a steel collar that encircles the revolving cylinder. Revolution of the spherical segment produces revolution of the cylinder by this sliding friction drive that has a contact of about one-half inch. The spherical steel segment can be moved about a horizontal axis in such a way as to shift the frictional driving surface from the center to the periphery of the spherical segment. This shift is capable of varying the speed from 60 to 360 r.p.m. This is an improvement upon the previous method¹ of changing the rate of revolution of the cylinder by varying the armature resistance of a D.C. motor.

In the old apparatus great difficulty was experienced in producing a rust-proof inner surface for the cylinder. In the present apparatus a "Micarta"† cylinder $\frac{1}{8}$ inch thick fits snugly within the steel cylinder and provides a smooth, rust-proof surface for the film of blood. The lower end of the cylinder is tapered from within outward to a knife edge. A chrome-plated copper cup slides up over the lower end of the cylinder, overlapping the cylinder by $1\frac{1}{2}$ inches. The space between the lower, sharp end of the cylinder and the inner wall of the stationary cup is less than 1 mm. The lower part of the cup is funnel-shaped and terminates in a central aperture $\frac{3}{4}$ inch in diameter, from which a tapered

†A plastic made by Westinghouse Electric Company.

collar extends downward. Over this tapered collar is slipped the neck of a glass cup with a similar taper. The junction between the ground-glass neck and the metal collar is sealed with stopcock grease, and the glass cup is held in position by two small springs extending from the glass cup to the bottom of the metal cup. Both the metal and the glass cups are jacketed separately to permit the circulation of water between the walls in order to maintain the blood at the desired temperature.

Fig. 1.—Photographs of oxygenator. Front and side views.

The greater portion of the space within the revolving cylinder is occupied by a closed, stationary cylinder, as in the previous model. Through the center of this closed cylinder passes a tube which is used to convey a mixture of oxygen and carbon dioxide at a rate of 5 liters per minute to the lower portion of the inside of the apparatus. The oxygen mixture then diffuses upward in close contact with the inner wall of the revolving cylinder. When using the apparatus for perfusion, a mixture of 95 per cent oxygen and 5 per cent carbon dioxide is used so as to maintain an approximately normal carbon dioxide content in the blood.

Blood is introduced at the top of the cylinder through a stainless steel tube having a 2.5 mm. bore. The tube is curved and its end is flattened so that it delivers a fanlike stream of blood against the inner wall of the revolving cylinder in the direction of revolution and tangential to the curved surface of the cylinder. The tube is locked in position on the inner stationary cylinder, but is detachable for cleaning. When blood is pumped through this inlet tube onto the upper part of the inner surface of the cylinder while it is revolving, a film of blood is established in a horizontal band about 4 inches high around the upper part of the cylinder. At the lower margin of this band the film of blood breaks up into vertical rivulets of blood approximately 0.5 cm. in width, spaced at intervals of 2 cm. Under these circumstances relatively small amounts of oxygen are introduced into the blood. Consequently, it was found necessary to prime the cylinder with blood in order to establish a film. This priming can probably be accomplished in a variety of ways. It was found simplest to wipe the vertical length of the cylinder with a gauze sponge while the cylinder is revolving and the blood is flowing in at the top. Once the film is established, it will remain as long as the cylinder is revolving and blood is flowing in at the top; but both the revolution of the cylinder and the flow of blood may be stopped simultaneously for brief intervals without the loss of the film.

The optimum rate of revolution of the cylinder is in the neighborhood of 250 r.p.m. Faster rates have not facilitated the introduction of oxygen into blood. With slower rates the film of blood on the inner surface tends to split up into rivulets when the flow of blood through the oxygenator is small. Foaming occurs only if air enters the tubing through which blood is being pumped into the oxygenator.

INTRODUCTION OF OXYGEN

The amount of oxygen that can be added to blood by this apparatus was determined in the following manner: Venous blood was continuously withdrawn from the superior vena cava of an animal and pumped into the top of the oxygenator. The oxygenated blood was pumped back from the cup at the bottom of the cylinder into the femoral artery in a central direction. The pumps used were of the constant injection roller type as modified by DeBakey² and driven by an electric motor.³ The rate of the pumps was varied by an armature resistance, and the speed of the motor was read directly on a speedometer. The output of the pumps was calibrated by measuring the delivery of blood at different rates of revolution after the experiment. Cats were used in five instances, Nos. 1 to 5, inclusive, in Table I; and dogs in six instances, Nos. 6 to 11. Several weeks prior to the experiments on the cats, the ribs overlying the pericardium were excised and the pericardium was sutured to the chest wall just beneath the skin. The pulmonary artery could thus be exposed and clamped without producing an open pneumothorax. In all the cats the pulmonary artery was completely occluded. During the period of occlusion the circulation of blood through the animal was maintained by the mechanical pumps, and the respiratory function of the lungs was performed by the oxygenator.³ To obtain a larger flow of blood dogs were used in the last six observations in Table I. In these animals

the pulmonary artery was not occluded. In observations Nos. 8, 9, 10, and 11, the dogs were allowed to inhale from a spirometer filled with 85 per cent nitrogen and 15 per cent oxygen in order to decrease the saturation of the venous blood with oxygen. In all the experiments sufficient heparin was given intravenously to prevent coagulation of the blood. Simultaneous samples of blood were withdrawn under oil from the tubes leading to and from the oxygenator. The samples were immediately analyzed for oxygen and carbon dioxide content and oxygen capacity. The determinations were made in duplicate. The greatest difference between duplicate samples in oxygen content was 0.15 volumes per cent, and in oxygen capacity it was 0.20 volumes per cent.

TABLE I

OBSERVATION NO.	OXYGEN CAPACITY (VOL. %)	SATURATION		OXYGEN ADDED TO BLOOD (C.C./100 C.C.)	BLOOD FLOW (C.C./MIN.)	OXYGEN ADDED TO BLOOD (C.C./MIN.)	CARBON DIOXIDE IN OXYGEN (%)
		% BEFORE	% AFTER				
1	16.75	57	99	6.88	130	8.94	5
2	17.01	36	99	10.57	240	25.37	0
3	14.51	58	93	5.19	255	13.23	6
4	14.76	72	95	3.52	270	9.50	5
5	14.23	41	99	8.35	285	23.80	5
6	17.32	72	96	4.11	370	15.21	5
7	21.90	73	92	4.24	375	15.90	5
8	21.19	48	82	7.39	380	28.08	5
9	22.03	40	72	7.04	395	27.81	5
10	17.13	32	64	5.41	420	22.72	7
11	21.87	64	95	6.71	455	30.53	5

The results are arranged in Table I in order of increasing blood flow. It can be seen that up to rates of 375 c.c. per minute the blood leaving the oxygenator is adequately saturated with oxygen at varying degrees of venous saturation. In three instances (Nos. 8, 9, 10) the saturation of the blood leaving the oxygenator was below 92 per cent. In one of these, No. 10, the blood was only 64 per cent saturated, but there was marked venous unsaturation; a gas mixture of 93 per cent oxygen and 7 per cent carbon dioxide was passed through the oxygenator instead of the usual mixture of 95 per cent oxygen and 5 per cent carbon dioxide. In this experiment the carbon dioxide content of the blood leaving the oxygenator was 51.23 volumes per cent, whereas in the other ten instances the carbon dioxide content varied between 42.83 volumes per cent and 30.59 volumes per cent. In Nos. 8 and 9 there was also a marked unsaturation of venous blood, and the flow was relatively large.

HEMOLYSIS

To maintain normal function when perfusing an isolated kidney it is probably important to avoid hemolysis in the blood used for perfusion.⁴ Similarly, in the perfusion of the entire body of an animal it must be equally important to avoid hemolysis. To determine the degree of hemolysis produced by the oxygenator, blood was allowed to flow into the apparatus by gravity from a 250 c.c. burette at a rate between 250 and 350 c.c. per minute (the range of blood flow

used to perfuse cats of average size). Blood was drained from the glass cup at the bottom of the oxygenator into a flask which was intermittently emptied into the burette which supplied blood to the oxygenator. The total volume of blood used in these observations was approximately 600 c.c. The temperature of the blood was maintained between 37.5° and 38.5° C. by the circulation of warm water through the double walls of the stationary metal and glass cups.

Fig. 2.—A, Relation of flow of blood through oxygenator to thickness of blood film. B, Relation of blood flow to time of exposure of film.

The blood used was obtained from a dog the day before the observations were made, and was kept in an icebox overnight. Coagulation was prevented by the addition of heparin. At the start of the observations, a sample of blood was placed in a Wintrobe hematocrit tube.² The blood was then passed continuously through the oxygenator with the cylinder revolving at 250 r.p.m. Samples of blood were removed and placed in hematocrit tubes every fifteen minutes, until the blood had circulated through the oxygenator for an hour and a quarter. Cells were separated from the plasma in the hematocrit tubes by centrifuging. The colors of the samples of plasma were then compared with the colors of a set of standard tubes of similar diameter containing known dilutions of completely hemolyzed red blood cells. It was found that up to thirty or forty-five minutes the plasma remained practically clear (i.e., faint straw color). From then on there was a steadily increasing rate of hemolysis. At the end of an hour and fifteen minutes of passage through the oxygenator, the plasma had a pronounced reddish tinge.

THE BLOOD FILM

The area available for the filming of blood on the inner surface of the vertical revolving cylinder is 4,000 sq. cm. This represents a 58 per cent increase in area over the oxygenator previously described.¹ The glass cup at the bottom of the oxygenator holds 12 c.c. of blood at an appropriate operating level. The volume of blood on the surface of the revolving cylinder was determined at different rates of blood flow as follows: A known quantity of blood

was placed in a graduated glass cylinder. The blood was then pumped from this cylinder into the copper cup at the bottom of the oxygenator from which it drained down into the glass cup. From the glass cup it was pumped back into the graduated glass cylinder, maintaining at all times a constant level of blood in the glass cup. The level of the blood in the graduated glass cylinder was then read at different rates of blood flow from 150 to 450 c.c. per minute. The volume of blood contained in the circuit at different rates of blood flow was thus determined. The revolving cylinder was then added to the circuit, and the determinations were repeated. In this manner the volume of blood on the sides of the revolving cylinder was determined at varying rates of blood flow. From these figures the thickness of the film and the time of exposure of the blood to oxygen were calculated. For example, 85 c.c. of blood are distributed over the surface of the oxygenator when the cylinder is revolving at 250 r.p.m. and blood is flowing through the apparatus at the rate of 250 c.c. per minute. Under these conditions the film of blood on the inner surface of the revolving cylinder is 213 microns thick, and the average time of exposure of the blood film to oxygen is 20.4 seconds.

The graphs of Fig. 2 summarize the observations made. Each point on the graphs represents the mean of six determinations. It was found that with rates of flow from 150 to 450 c.c. per minute the depth of the blood film was directly proportional to rate of blood flow (Fig. 2A). The time the film of blood was exposed to oxygen on the inner surface of the revolving cylinder decreased, but at a progressively diminishing rate, as the flow of blood through the apparatus increased from 150 to 450 c.c. per minute (Fig. 2B). Both the greater depth of the film and the decreased time of exposure will tend to interfere with the absorption of oxygen by the blood. Therefore, at any given unsaturation of the blood entering the oxygenator, it is to be expected that, as the rate of blood flow increases, a point will be reached at which the blood leaving the oxygenator will no longer be adequately saturated with oxygen. That such a point has not been reached with degrees of venous oxygen unsaturation within the normal range at rest and a blood flow as great as 450 c.c. per minute is indicated by observation No. 11, Table I.

SUMMARY

An oxygenator capable of introducing as much as 30 c.c. of oxygen per minute into blood has been described. The apparatus is designed to accommodate rates of blood flow from 100 to 500 c.c. per minute. Up to 300 c.c. per minute, the blood leaving the oxygenator will be adequately saturated with oxygen even with marked degrees of venous unsaturation; and at rates of flow up to 450 c.c. per minute if the venous unsaturation is within the normal range. The apparatus is simple in construction and easy to operate. Foaming of the blood does not occur, and hemolysis is slight in periods up to forty-five minutes of operation.

A DEVICE FOR FIXING THE BRAIN AND SPINAL CORD IN ONE PIECE*

THEODORE S. ROSEN, M.D., AND GEORGE W. LUBINSKY, A.B.
NEW YORK, N. Y.

AFTER removing the brain and spinal cord as a single specimen, it is often found difficult to restore them in their proper relationships. In an ordinary brain jar, or even in a larger receptacle, the spinal cord frequently becomes twisted and its anatomic features are distorted. The following simple apparatus was devised to obviate this difficulty:

A glass tank (the type used for household aquariums are easily obtained and relatively inexpensive), 25 by 10.5 by 10 inches in size, is used as a receptacle for primary fixation. A glass cover is fitted over the top of the tank. A metal framework, consisting of two separate parts, as pictured in Fig. 1, is placed within this container which has been partially filled with 10 per cent formalin. The purpose of the framework is to provide a suitable crossbar at either end of the tank from which a brain may be suspended and hang freely, and two properly placed grooves along which the respective spinal cords may be extended in proper alignment with the given brain.

The framework is constructed from two pieces of galvanized wire, $\frac{1}{8}$ inch in diameter and 130 and 95 inches in length, respectively. These are bent in a continuous pattern, as seen in Fig. 2, with the aid of vise, pliers, and hammer. Each division of the framework is 7 inches high and 9 inches wide, and provides a series of crossbars resting on uprights, approximately $3\frac{1}{2}$ inches apart. Each crossbar except the first has two grooves an inch wide and an inch deep which lie approximately $1\frac{1}{4}$ inches apart. These are the grooves in which the spinal cords are supported. The two divisions of the framework are so devised as to form one continuous pattern when placed end to end in the tank. In this fashion, the complete framework has one ungrooved crossbar available at each end of the tank, from which a brain may be suspended and hang freely by means of a loop of thread or metal hook. The respective cord of each of the brains may then be placed in the two grooves of the framework and thereby kept in good alignment with the brain.

Received for publication, September 13, 1940.

Fig. 1.—Glass household aquarium with brains and their attached spinal cords supported in grooves of wire framework.

Fig. 2.—Framework consisting of two lengths of wire bent into continuous pattern.

The brain is shifted on the crossbar, so that the spinal cord lying in the groove forms a continuous column with the brain stem. Having the framework in two portions permits the removal of one of the two brains without disturbing the other, or the addition of a fresh specimen to the tank when one is already in place.

A RAPID METHOD FOR STAINING BLOOD SMEARS IN DETERMINING OPSONOCYTOPHAGIC INDICES*

AMEDEO BONDI, JR., M.S., PHILADELPHIA, PA.

BECAUSE of the unsatisfactory results obtained from staining blood smears for opsonocytophagic indices with Hasting's stain as recommended by Huddleson and co-workers,⁵ many new methods have recently been reported (Cape and Jaffe²; Flinn⁴; Bruner and Edwards¹; Calder³). Satisfactory staining for this work, in addition to being simple, should permit accurate enumeration of the organisms ingested by phagocytes. Polymorphonuclear neutrophils must be readily recognized, and phagocytized bacteria must not be mistaken for cytoplasmic granules. Some of the newer methods (Flinn⁴), while satisfactory, require stains or reagents which are not usually available to most routine laboratories.

The method reported here has been used in this laboratory with considerable success. Citrated blood is mixed with a saline suspension of *Brucella* cells in the usual manner and incubated at 37° C. for thirty minutes. Blood smears are made and dried quickly to prevent shrinkage of white blood cells. These are then put through the flame of a Bunsen burner four times and allowed to cool. The fixing of smears by flaming is very important and may require practice before the right amount of flaming is obtained. If not flamed sufficiently, smears will tend to wash off the slide, whereas overflaming will result in smears too deeply stained.

The fixed smears are covered with 10 per cent Ziehl-Neelsen carbolfuchsin. This stain is prepared by diluting $\frac{1}{10}$ the Ziehl-Neelsen carbolfuchsin used for tubercle bacillus staining with distilled water and filtering. At the end of two minutes the slides are washed gently with tap water to prevent the dye from precipitating on the slide, and then allowed to dry.

By this method *Brucella* and the nuclei of the phagocytes stain deep red. The cytoplasm of the latter is a light pink; granules are not stained. Red blood cells stain weakly. Phagocytized bacteria appearing against the lightly stained cytoplasm are easily counted.

This method has also proved satisfactory for phagocytosis studies with streptococci, staphylococci, pneumococci, *H. influenzae*, and *H. pertussis*.

I wish to acknowledge with gratitude the advice of Dr. John A. Kolmer who suggested the use of carbolfuchsin.

THE STANDARDIZATION OF CERTAIN FACTORS IN THE CUTANEOUS "VENOSTASIS" BLEEDING TIME TECHNIQUE*

A. C. IVY, PH.D., M.D., DOROTHY NELSON, M.S., AND GLADYS BUCHER, M.S.
CHICAGO, ILL.

UNTIL all the factors concerned in hemostasis are known and can be tested individually by adequately quantitative methods, the determination of bleeding time will remain a necessary and valuable test of the "bleeding tendency." A disturbance of hemostasis obviously involves defects in either the process of coagulation, or the capillaries, or a combination of both. The presence or absence of a "bleeding tendency" would not necessarily be revealed even if one were to test for a coagulation defect by adequate methods and for capillary fragility by the suction or tourniquet technique. It is possible that a defect in coagulation might be neutralized by a compensatory response in the capillaries or vice versa. In other situations, however, the imperfections of one might augment those of the other. It is desirable, therefore, both for physiologic experimentation and for clinical purposes, to have a reliable method for the determination of bleeding time in order to study the end result of the relationships between the defects in coagulation and in the capillaries or peripheral tissues.

For this reason, we have undertaken a study of the reliability and limitations of the venostasis bleeding time test.^{1, 2} This test was selected because venostasis usually prolongs the bleeding time of normal subjects¹ and hence tends to accentuate differences and defects that otherwise might be missed.

The tests reported in this study were performed exclusively on the bleeding tendency of the skin. It should be remembered that the results are not necessarily applicable to the mucous membranes and other tissues.³

EXPERIMENTAL

The Lancet.—The Sharpe and Smith lancet was used. It was selected because we believed the wide base might serve to distribute the pressure more equally. In a preliminary study it was found that setting the blade length at 2.5 mm. below the level of the rim of the base resulted in too great a percentage incidence of "no bleeding." The use of a 3.0 mm. blade length decreased but did not abolish the number of "no or zero bleeding" cuts.

Another difficulty was the sharpness of the blade. Cuts made with a sharp blade bleed more freely than those made with a dull blade. The blades were kept sharp with very fine pumice and a leather strap. If sharpened too frequently, the metal is worn away so that the thicker portion of the blade remains.

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Received for publication, September 21, 1940.

New lancets in a single shipment were found to be well standardized as to width, but not as to thickness. Ideally, thin and replaceable blades, as in the Tocantins' instrument,³ should be employed.

Control of Pressure.—Standardization of the depth of the puncture is one of the most essential features of a good bleeding time test. It seemed probable that control of the pressure placed upon the lancet before the blade is released might contribute to the uniformity of the punctures.

In order to control pressure, the lancet was mounted on a framework to which an arm rest was attached. The sliding bar which held the lancet was so weighted that when the lancet was placed on the average arm, its rim depressed the skin approximately 1 cm. This amount of pressure gave exceptionally short bleeding times in subjects with a well-developed pronator muscle and little subcutaneous fat. In these cases the skin was not depressed 1 cm. by the weighted lancet, and it became evident that a constant pressure did not give the desired uniformity of the punctures. We, therefore, devised a gauge for the lancet that would indicate when the skin was depressed exactly 1 cm., and when necessary manual pressure was added till that depth was reached. This procedure resulted in unduly long bleeding times in the very muscular subjects. It is obvious, then, that neither the application of the same amount of pressure in all cases nor the identical depression of the peripheral tissues was able to insure punctures of equal depth.

With the mechanical refinements used, the results showed a slight decrease in variability as compared with those obtained using the ordinary clinical procedure. However, the improvement was within the experimental error and hence was not significant. From this we conclude that with experience one can acquire a judgment in regard to pressure that is about as accurate as these mechanical devices for the production of uniform punctures.

The area of skin in which the punctures were made. With the subject seated and his forearm (left) in the supine position, the area over the pronator (lateral aspect of forearm below the cubital fossa) was washed gently with 95 per cent alcohol. (We have found that either forearm may be used.) The lancet was sterilized with alcohol and dried. After any hyperemia that may have occurred from the alcohol wash had disappeared, the pressure in a sphygmomanometer cuff about the arm was raised to 40 mm. Hg. A hemostat was used to prevent leakage of air from the cuff through the inflation bulb. The puncture or punctures were then made.

Since we were interested in comparing bleeding times in the same individual, it was necessary to make a number of punctures. Five series of two punctures were made on our 88 subjects as follows: with the pressure in the cuff at 40 mm. Hg, a puncture was made, and then five seconds later a second puncture was made, not less than one inch from the first puncture. The blood collected at each puncture was blotted with filter paper at ten-second intervals, timed with a stop watch. The filter paper was not pressed so firmly as to open the wound. The bleeding time is easily determined by multiplying the number of drops of blood on the filter by ten seconds.

After bleeding from the two punctures had ceased, the cuff was deflated and the arm was very mildly exercised. Then two more punctures were made an inch apart. This procedure was repeated until the bleeding time of five sets of two punctures each had been determined. This provided the data for analysis.

Subjects.—Eighty-eight subjects, 58 men and 30 women, of medical school age were used. Retests were made on 31 subjects, some of them being tested on several occasions.

Three additional subjects were excluded from this study because their mean bleeding times were definitely abnormal (*vide infra*). For some unknown reason an occasional subject continued to ooze blood-tinged serum for a relatively prolonged period. Data from such subjects were not used.

RESULTS AND DISCUSSION

The "*clinically normal*" maximum venostasis bleeding time from a single puncture. In Fig. 1 the 1,280 readings on the 88 subjects are distributed according to frequency. The bleeding times ranged from 0 to 310 seconds. The upper limit for "*the clinically normal*" found by Ivy, Shapiro, and Melnick¹ was 240 seconds. According to our results, 240 seconds includes 99.54 per cent of the readings. It is our belief that the few bleeding times above 240 seconds were due to striking a hidden vein because they were not typical of the other bleeding time measures obtained from the same individuals. Thus, 240 seconds as a "*clinically normal*" maximum venostasis bleeding time for a "*one puncture test*" is confirmed for the age group studied, unless a vein is accidentally punctured.

In setting a "*clinically normal*" maximal "*venostasis*" bleeding time at 240 seconds on the basis of a "*one puncture test*," patients with a mild to moderate "*bleeding tendency*" may be diagnosed as normal. This is likely because of the errors inherent in any relatively crude method. However, the errors usually tend to cancel each other when a number of tests are made. Hence the mean of several bleeding times more closely represents the true status.

The "*clinically normal*" mean or average venostasis bleeding time. In Fig. 1 the mean bleeding times of the 88 subjects are distributed according to frequency. The mean bleeding time of the subject who had the best cutaneous hemostatic mechanism by this test was twenty seconds, and that with the poorest was 125 seconds. Thus, a patient would be "*clinically abnormal*" if the mean bleeding time as determined by the test outlined above was significantly greater than 125 seconds.

COMMENT

From the preceding discussion of the results the advantage of making more than one test of bleeding time is obvious. However, the patient and the time factor have to be considered. The question then arises: What is the least number of punctures required to yield a reasonably reliable mean cutaneous venostasis bleeding time? A subsidiary question is: When two punctures are made, one within five seconds of the other, does the making of the first puncture modify significantly the bleeding time of the second puncture?

What is the least number of determinations required to yield a reasonably reliable cutaneous "*venostasis*" bleeding time? In Table I are listed the various

means and medians that may be used as a bleeding score. Medians were proposed to eliminate extreme readings which weight the means.

As can be seen from Fig. 1 the frequency of zero bleeding times is greater than that of any other bleeding time. Table II gives the distribution of the zero readings over the ten successive punctures. Due to the influence the zeros would have on the variability of the means or medians, these were recalculated using the first 3, 4, or 6 individual punctures that bled instead of the first 3, 4, or 6 punctures made (Table I).

Fig. 1.—Distributions of bleeding times
A = 1,280 readings on 88 normal subjects
B = Means of 10 readings on 88 normal subjects.
Abscissae = Time in seconds
Ordinates = Number of readings

Regarding each of the listed means and medians in Table I as the result of a proposed bleeding time test, four criteria will be used to examine their relative value: (1) their similarity to the mean of 10; (2) their reliability as judged by the test-retest method; (3) their reliability as judged by the deviations from their means; and (4) the practical consideration which calls for the shortest test possible.

The deviations of each measure from the mean of 10 are shown in Table I, and the significance of the differences is indicated by the critical ratios. The mean of the first three odd punctures that bled is almost exactly the same as the mean of 10, and the median of the first four that bled shows only a slight difference. Since a critical ratio must be 2.60 or more to indicate a statistically significant difference with this number of cases,⁴ it may be seen that the mean of the first 6 that bled, and the mean of the middle 6 are significantly larger than the mean of 10. The mean and the median of the first 4 made, and also the median of the first 3 made are significantly smaller than the mean of 10. The directions of these deviations suggest that the exclusion or preponderance of zero scores is responsible for the extent of variation.

The correlation of each of these measures with the mean of 10 is another demonstration of similarity. All the correlations are spuriously high because the individual readings from which each of the smaller means or medians is derived are also included in calculating the mean of 10. However, the correlations will not misrepresent the facts if the relationships are interpreted as showing the similarity of 128 bleeding time scores computed by each of two methods, and not as indicating the accuracy with which, knowing the mean of 10, one could predict the compared mean or median that would be obtained if the necessary six, four, or three additional punctures were made.

TABLE I

MEASURES OF BLEEDING TIME DERIVED FROM VARIOUS NUMBERS OF PUNCTURES. THE COMPARISON OF EACH WITH THE MEAN OF 10 PUNCTURES, AND THE SELF-CORRELATION OF EACH AFTER A RETEST

MEASURE OF BLEEDING TIME	TIME IN SECONDS	CORRELATION WITH MEAN OF 10	DIFFERENCE FROM MEAN OF 10	C.R.* OF DIFF. FROM MEAN OF 10	CORRELATION TEST-RETEST
Mean of 10 punctures	61.56 ± 2.1				+0.30
Mean of first 6 made	59.69 ± 2.3	+0.90	1.87	1.85	+0.34
Mean of first 6 that bled	66.95 ± 2.3	+0.87	5.39	4.73	+0.13
Mean of first 4 made	56.64 ± 2.7	+0.74	4.92	2.68	+0.30
Mean of first 4 that bled	65.23 ± 2.5	+0.77	3.67	2.25	+0.17
Median of first 4 made	53.28 ± 2.8	+0.74	8.28	4.40	+0.36
Median of first 4 that bled	62.19 ± 2.6	+0.73	0.63	0.35	+0.36
Median of first 3 made	48.28 ± 2.6	+0.69	13.28	6.95	+0.55
Median of first 3 that bled	58.13 ± 2.5	+0.65	3.43	1.72	+0.29
Mean of middle 6 made	64.06 ± 2.6	+0.94	2.50	2.61	+0.29
Mean of first 3 odd that bled	61.41 ± 2.4	+0.91	0.15	0.15	+0.33

$$*C.R. = \text{Critical ratio} = \frac{\text{Obtained difference}}{\text{Sigma of difference}}$$

$$\text{Sigma difference} = \sqrt{(\sigma m_1)^2 + (\sigma m_2)^2 - 2r\sigma m_1\sigma m_2}$$

r = Coefficient of correlation

Obviously, each addition of identical data raises a correlation. Therefore, the means of 6 would be expected to show the highest correlation in this particular situation. *It is thus of great interest to note that the mean of the first 3 odd punctures that bled has a correlation as high as the means whose correlations involved twice as many identical readings.*

The reliability of a test shows the degree of consistency with which it measures. One indication of reliability is a high correlation between two sets of results when, under controlled conditions, the test is repeated on the same individuals. Unfortunately, this "test-retest" information is available for only 31 cases. The correlations are given in Table I; they are all unduly low because the narrow limits of the data included in this study do not permit the range of variability between one individual and another which is necessary for any test to demonstrate its maximum value. Therefore, the significance of the "test-retest" correlations is for comparative purposes only. It will be noted that the zero scores are again a determining factor, since the highest correlation is the median of the first 3 punctures made, where the incidence of zero readings predominates, and the correlations of the means of data from which the zeros are omitted, are conspicuously inferior.

There was no consistent trend toward a longer or shorter bleeding time when the test was repeated on 31 subjects. The mean bleeding times of the 31 first tests were about the same as the means of the 31 repeat tests. The means or medians of 10, 6, 4, or 3 punctures for the 31 cases varied from 50 to 65 seconds in both the first and repeat tests. It was apparently mere chance as to which was the higher, each one being slightly superior as gauged by about half of the measures. As indicated by the low correlations (Table I) there was little consistency between the first and repeat tests of each individual. This is to be expected with such a homogeneous group.

TABLE II
INCIDENCE OF ZERO READINGS

CONSECUTIVE PUNCTURES	1	2	3	4	5	6	7	8	9	10
% of total (128 cases)	20	19	9	9	11	10	8	8	6	5
% of men (53 cases)	21	16	10	8	7	16	12	8	5	7
% of women (30 cases)	19	21	9	10	15	5	5	7	8	5

Another criterion of reliability is a small standard error or deviation of the mean of a series of tests. The standard error, or sigma, of a mean (σ_m) is a measure of variability which indicates the range within which a "true mean," or the mean of an infinite number of cases, would have a 67 per cent chance of falling. It is also the range within which 67 per cent of the means would fall if other sample groups of the same size were tested under conditions identical to those producing the original mean. Therefore, if the range designated by the sigma of a mean is small, the test is consistent.

The standard errors of the means and medians listed in Table I were obtained by assigning to each person a bleeding time based on the mean of 10 punctures or the median of 3, etc., and finding the sigmas of the mean of the 128 bleeding times so defined. They are not strikingly dissimilar. It may, therefore, be concluded that if one wishes to determine the average bleeding time of a group of about a hundred people, any of the proposed tests would offer approximately the same degree of reliability. However, there would be a trend in the direction of greater consistency in the measures whose individual scores were based on a larger number of punctures. An exception to this trend is noted in favor of the mean of the first 3 odd punctures that bled.

This material on standard errors of the means or medians of 128 cases gives no indication of the reliability of the various means or medians for determining the bleeding time of individual persons, which is of much greater clinical importance than the measurement of groups. *The standard error of a mean or median of the punctures made on any subject is the range within which the chances are 2 to 1 that his "true bleeding time" would lie if established by an infinite number of punctures.* Naturally this range differs in individuals. By finding the average standard error of the 128 means and medians, a comparison can be made of their reliability as individual bleeding time tests. The mean standard errors are listed in Table III, together with their correlations and differences from the average sigma of the means of 10.

The formula for deriving a sigma of the mean being

$$\frac{\text{Sigma of distribution}}{\sqrt{\text{Number of cases}-2}}$$

when there are 10 cases, and

$$\frac{\text{Sigma of distribution}}{\sqrt{\text{Number of cases}-3}}$$

when there are less than 10, it can be seen that the measures based on fewer than 10 punctures were heavily penalized.⁵ It may be argued that such an inequitable comparison is of little value, but this is not the case, since the issue will be encountered every time one investigates the significance of a difference between bleeding measures made under varied conditions, as, for example, before and after treatment.

TABLE III

RELIABILITY OF THE MEASURES AS GAUGED BY INTERNAL CONSISTENCY

MEASURE OF BLEEDING TIME	MEAN SIGMA OF MEANS	DIFFERENCE FROM SIGMA MEAN OF 10	C. R.	CORRELATION WITH SIGMA MEAN OF 10
Mean of all 10	14.73 ± 0.51			
Mean of first 6 made	22.51 ± 0.92	7.78	14.88	0.80
Mean of first 6 that bled	17.15 ± 0.86	2.42	5.69	0.96
Mean of first 4 made	31.09 ± 1.54	18.61	12.48	0.57
Mean of first 4 that bled	29.57 ± 1.53	14.84	13.86	0.60
Median of first 4 made	33.40 ± 1.60	18.67	13.24	0.51
Median of first 4 that bled	31.72 ± 1.60	16.99	12.67	0.62
Median of first 3 made	31.33 ± 1.94	16.60	9.70	0.56
Median of first 3 that bled	29.02 ± 1.84	14.29	8.82	0.53
Mean of first 3 odd that bled	25.31 ± 1.71	10.58	6.82	0.45

The differences between the mean sigmas of the means of 10 and the mean sigmas of all the other measures are statistically significant. The large critical ratios are due to the spuriously high correlations (see footnote to Table I). It can be seen by inspection of the table that except for the sigmas of the means of six punctures, the differences between any two of the other measures would not be significant unless equally high correlations exist between them. The sigmas of the means of the 3 odd punctures might also be an exception. However, statistical analyses were not made to confirm this.

The standard errors of the means and medians of individual cases are open to criticism from a statistical standpoint because the formulas from which they are calculated are based on the assumption that the data fall into a "normal distribution curve." The curve obtained by plotting all the raw scores, as shown in Fig. 1, epitomizes the skewed frequency which was typical of nearly all the individual curves. Probably the most important factor in causing this marked positive skew was the length of the lancet blade. Fig. 1, showing the curve of the means of 10 punctures, illustrates the fairly normal distribution characteristic also of the other means and medians.

To eliminate all errors arising from the asymmetrical distribution, the data in Fig. 1 were also analyzed in terms of per cent, using the means of 10 as the point of reference. The 128 cases were divided into two groups, those having a mean bleeding time (mean of 10 punctures) of one minute or less and those

having a mean bleeding time between one and two minutes. The per cent of these groups with a bleeding time of one, two, or three minutes on the basis of the other means and medians is shown in Table IV.

TABLE IV

COMPARISON OF SHORTER TESTS WITH THE MEAN BLEEDING TIME OF 10 PUNCTURES

MEASURE OF BLEEDING TIME	A % OF PERSONS WHOSE BLEEDING TIME IS 0-60" (MEAN OF 10 PUNC- TURES) HAVING B. T. 1', 2', OR 3'			SCORE*	B % OF PERSONS WHOSE BLEEDING IS 61-120" (MEAN OF 10 PUNC- TURES) HAVING B. T. 1', 2', OR 3'		
	1'	2'	3'		1'	2'	3'
Mean of first 6 made	91	9	0	169	16	78	6
Mean of first 6 that bled	78	22	0	160	10	82	8
Mean of first 4 made	86	14	0	150	32	64	4
Mean of first 4 that bled	76	24	0	150	20	74	6
Median of first 4 made	88	12	0	144	36	56	8
Median of first 4 that bled	79	21	0	145	26	66	8
Median of first 3 made	93	7	0	145	44	52	4
Median of first 3 that bled	85	15	0	147	32	62	6
Mean of first 3 odd that bled	86	14	0	152	31	66	3

*This score is the sum of the per cent values in column 1A and column 2B. It is an arbitrary measure for evaluation.

The measures which included zero readings show the greatest per cent of agreement with the group which had a bleeding time of one minute or less (on the basis of the mean of 10), and the measures excluding the zeros were in better agreement with the group having a bleeding time between one and two minutes. By summing the per cent values listed for each test in column one (1') of the first group with those of column two (2') of the second group, an arbitrary score was devised by which to evaluate the tests. As was pointed out in the discussion of the correlations of the means, the inclusion of the same raw data in computing the two measures, gives an advantage to those based on the largest number of punctures. As in the previous case an exception appears in favor of the mean of the first three odd punctures that bled.

TABLE V

BLEEDING TIME AVERAGES OF THE SUCCESSIVE PUNCTURES

SUBJECTS	1	2	3	4	5	6	7	8	9	10	TOTAL
All cases	47.4	53.7	55.6	64.9	53.0	76.9	59.4	67.9	62.5	71.2	61.5
All cases—zeros excluded	59.5	66.1	61.4	72.3	59.6	85.6	64.6	73.6	66.6	75.3	68.4
Men only	43.4	56.7	60.6	63.3	55.9	77.0	62.0	70.8	70.6	72.5	63.2
Women only	48.4	50.9	51.0	67.6	50.4	76.7	57.0	65.2	55.1	70.0	59.2

The fourth consideration in selecting one of the proposed bleeding time measures is the obvious advantage of brevity. The assumption that the test would be improved by increasing the number of punctures was invalid in this case. As is shown in Table V there is a decided trend toward a longer bleeding time as the test proceeded. This is also shown by the fact that the mean of the first 5 punctures (128 cases) is 54.38, and the mean of the last 5 is 68.59. The

difference between the two means is statistically significant, since the critical ratio is 5.24. *A progressive hyperemia seems to be the most pertinent interpretation of this cumulative error.*

Because the first two punctures included more than a third of the zero scores, and the last two were unduly prolonged, the means of the middle six punctures were computed (see Table I) and used as a standard in place of the means of 10. The substituted values did not gain sufficiently in uniformity to offset the statistical disadvantage of omitting two-fifths of the readings. This standard was, therefore, less satisfactory than the means of 10.

Fig. 2.—Average bleeding times of successive punctures.
Abscissae = Successive punctures.
Ordinates = Mean bleeding time in seconds. Zero readings excluded.
M = Mean of all punctures. Zero readings excluded.

Does a first puncture modify the bleeding of a second puncture made five seconds later? Table V and Fig. 2 also reveal another source of error, where one puncture follows another in five seconds. Apparently the first puncture of each pair was sufficiently traumatic to cause a transitory hyperemia or change, probably due to an axone reflex. The only exception to the sharp alternations is puncture 2, when the zero readings are included. When all the first punctures, the odd tests, are compared with the second, or even tests, there is a significant difference between them. The mean of the odds is 56.88, the mean of the evens is 68.12, and the critical ratio is 5.70.

It is very interesting that in spite of the marked difference between them, the odd and even punctures have a correlation coefficient of +0.63. A correlation of this type constitutes the "split-half" technique for determining the reliability of a test. Considering the similarity of the data, this is a fairly high correlation, certainly far superior to the "test-retest" relationship. The fact that a correlation of single punctures made within five seconds of each other is twice as high as the correlation of the means of 10 punctures made on different days may be interpreted in two ways. It may mean that the control of all variables, except the site of puncture, as was the case with the simultaneous readings, minimized certain physiologic fluctuations; on the other hand, it may simply indicate that sufficient errors arise in the long test to impair its reliability.

The reason for making the readings in pairs was to save time. *Analysis of the results shows clearly that more uniform results are to be expected from making the punctures one at a time.*

Inspection of Fig. 2 suggests the use of the first three odd punctures that bled as the most consistent test of bleeding time. This measure compared favor-

ably with the others: (1) the 128 means thus obtained were almost identical to those which resulted from averaging 10 punctures; (2) reliability judged by the "test-retest" method was about average; (3) reliability based on deviations was relatively high; and (4) a three-puncture test is undeniably short. It seems, therefore, to fulfill all the requirements stipulated for the evaluation of the proposed bleeding time measures.

Recommendation.—Using the lancet we employed, it is recommended that a relatively reliable mean venostasis bleeding time may be determined as follows: (1) The pressure in the cuff is elevated to 40 mm. Hg. The puncture is made. If bleeding occurs, the bleeding time is recorded; if it does not, nothing is recorded. The cuff is decompressed. (2) Five minutes later the cuff is inflated again, and the puncture is made. If bleeding occurs, the bleeding time is recorded; if it does not, nothing is recorded. This procedure is repeated until three bleeding times have been recorded. The mean bleeding time is the average of the three bleeding times. In our 88 subjects the mean bleeding time of three punctures was 61.41 ± 2.43 , as compared to the mean of 10 punctures which was 61.56 ± 2.08 . It should, however, be recalled that our three punctures were the first punctures of each of three pairs and were not made singly as recommended above.

SUMMARY

Mechanical refinements directed toward increasing the accuracy of the use of a spring, flat-bladed lancet in the hands of an operator of some experience did not prove to be of significant value. The blade of the lancet was set at 3 mm. Venostasis of the forearm was produced by placing a sphygmomanometer cuff about the arm and inflating it to 40 mm. Hg pressure. The skin over the pronator was punctured with the lancet. The blood was gently blotted at ten-second intervals until bleeding ceased.

A study of the reliability of the venostasis bleeding time technique was made on 88 "normal" subjects by a multiple skin puncture method. Five pairs of punctures of the skin were made on each, the second puncture of the pair being made five seconds after the first. The cuff was deflated and the arm was moved about to restore circulation between each pair of tests. The subjects included 58 men and 30 women from about 21 to 40 years of age.

A "clinically normal" maximum venostasis bleeding time of 240 seconds for a "one puncture test" was confirmed. A "clinically normal" maximum mean venostasis bleeding time of 125 seconds was found on making 10 punctures in each of the 88 subjects. A "clinically normal" mean venostasis bleeding time of 61.56 ± 2.08 seconds was obtained for this group of 88 subjects. No significant sex difference in the mean bleeding time was found. The results on 31 subjects who were retested showed no significant variation in the mean bleeding time.

Statistical analysis of the results showed (a) that the second puncture of each pair bled significantly longer on the average than the first, (b) that the mean bleeding time of the last 5 punctures was significantly greater than the first 5, and (c) that a relatively reliable mean bleeding time for one setting may be

obtained by making one puncture during each inflation of the cuff, and averaging the time of the first three that bleed.

CHEMICAL

HEMOGLOBIN ESTIMATION WITH UNDILUTED REDUCED BLOOD*

GEORG BARKAN, M.D., BOSTON, MASS.

SAHLI¹ in 1902 first used the color intensity of acid hematin as a basis for the clinical estimation of hemoglobin. The original Sahli instrument has seen many modifications and reconstructions, e.g., the Anteuirith-Königsberger hemometer,² the Newcomer hemometer,³ and the Haden-Hausser instrument⁴ have been introduced. In Europe there has been constructed in recent years the Zeiss-Ikon hemometer⁵ in addition. All these models, like the original Sahli instrument, use the brown color of acid hematin which has to be compared with a standard color (fluid or glass). This "Sahli principle" is probably the one most commonly used for hemoglobin estimation in routine work. It is well known that the brown color which develops from addition of acid to the blood depends on various reactions. They in turn are supposed, as a whole, to depend on the hemoglobin content and hence, if standard conditions are used, to lead to a color intensity which is proportional to the hemoglobin previously present in the blood.

Newcomer³ in 1930 published a very profound investigation about the optical behavior of acid hematin. His experience suggested that the curve of color development against time had a rather regular slope. The question remained whether the blood solution after being acidified really "acts for the present purpose as if it formed a true solution" (Newcomer³). In a series of publications⁶⁻¹¹ during the last few years, I was able to demonstrate that the colloidal character of acid hematin solutions can very easily be evidenced by the influence upon the hemometric readings of different experimental conditions. In experiments with human blood I could show deviations as high as 14 per cent in the hematin color intensity as compared with the photometrically determined oxyhemoglobin value. I wrote (1937) with reference to the colorimetry of the hematin color, "the latter is a term of very doubtful value. It should disappear from the clinic as a measure of the hemoglobin content."¹⁰ Heilmeyer and von Mutius¹² (1938), in comparing the hematin method with other more reliable methods of hemoglobin determination, also found an inaccuracy up to 11 per cent and so did Humperdineck.¹³ Heilmeyer and von Mutius state "that the method should be eliminated as far as possible for scientific purposes"¹²; they are of the opinion that the procedure might still be satisfactory for medical practice because of the lack of any other reliable and handy method.

In 1937⁹ I pointed out that the colorimetry of reduced hemoglobin, introduced by Bürker,¹⁴ and in connection with the use of the Pulfrich photometer recommended by Heilmeyer,¹⁵ could well be simplified with a handy instrument

*From the Evans Memorial Massachusetts Memorial Hospitals, and the Department of Biochemistry, Boston University School of Medicine, Boston.

Received for publication, March 31, 1941.

for routine work. In 1938 I learned that such an instrument had been proposed independently by the Danish physician Dr. M. Philipsen and was just brought on the market.¹⁶ After having carried out comparative investigations with the new instrument (Sieca hemometer*), a brief report in connection with my previous publications in that field may be justified.

Fig. 1A.

Fig. 1B.

SICCA HEMOMETER

One of the advantages of the new method is that the blood need not be measured but simply taken in the hand pipette (Fig. 1A). Without being diluted it is reduced, hemolyzed, and stabilized by addition of a trace of a reagent powder containing sodium hydrosulfite, saponin, oxalate, and sodium chloride (Fig. 1B).

The main part of the hemoglobinometer is the wedge-shaped chamber. It is formed by a glass base plate and a covering glass piece ground to form a wedge-shaped hollow. The reduced blood specimen in the hand pipette is directed into the wedge-shaped chamber, thus forming a blood color wedge.

*Manufactured by the Testa-Laboratorium, Vedbaek, Denmark, U. S. A. Pat. No. 2,163,467.

The wedge chamber lies on the scale plate which has a window showing the standard color. Both blood and standard are illuminated from beneath by an electric lamp, the light passing some particularly selected filters. Fig. 2 shows the pattern of the apparatus. For determining the hemoglobin content the chamber is moved along until the specimen color corresponds to the standard. A marked line on the glass base plate indicates the hemoglobin value on the scale. The instrument is adapted to two ranges of hemoglobin content. This involves the use of two color standards, one of which is kept covered by a shutter. The standard most appropriate is uncovered by turning the wheel marked with an arrow. The arrow automatically points to that side of the scale to be read. An additional wedge ground to double height and marked "2" may conveniently be used for low hemoglobin values. When using this wedge all readings have to be divided by two.

TABLE I

STANDARDIZATION OF SICCA HEMOMETER WITH PHOTOELECTRIC OXYHEMOGLOBIN DETERMINATIONS

(Comparison With Hemoglobin Values Obtained From Blood Iron)

NUMBER	SICCA READINGS (MEAN OF 5-10) SCALE PARTS	HEMOGLOBIN (FROM SICCA) GM./100 C.C.	O ₂ HB. (PHOTOELECTR. EVELYN) GM./100 C.C.	HEMOGLOBIN (FROM BLOOD IRON WONG-WALKER) GM./100 C.C.
1	87.0	12.7	12.8	13.4
2	74.3	10.9	11.5	11.3
3	101.6	14.9	15.2	15.2
4	87.0	12.7	12.1	12.8
5	104.0	15.2	14.8	14.8
6	65.0	9.5	9.4	9.5
7	102.7	15.0	15.1	15.1
8	81.4	11.9	12.4	11.9
9	103.5	15.1	14.5	14.2
10	100.0	14.6	14.0	13.7
11	97.9	14.2	14.0	14.9
12	100.8	14.8	14.6	14.9
13	81.7	12.0	12.1	11.6
14	94.3	13.8	14.3	13.7
15	98.6	14.4	14.2	13.7
16	88.9	13.0	13.5	13.2
17	75.1	11.0	10.4	10.7
18	85.9	12.6	12.5	13.1
19	111.7	16.4	16.7	16.4
20	87.9	12.9	13.7	13.1
21	100.9	14.8	15.3	14.0
22	91.2	13.3	12.7	13.1
23	90.0	13.2	13.2	13.2
24	82.3	12.0	12.1	12.5
25	108.1	15.8	16.0	16.1
Average	92.07		13.48	13.44

Therefore 100 scale parts Sicca = 14.64 grams of hemoglobin per 100 c.c.

STANDARDIZATION

Because of a mistake in shipping, I had to build in a new set of filters in the instrument I used first. Thus a restandardization of the hemometer became necessary. Twenty-five samples were taken from different patients and protected against coagulation by adding some oxalate or liquid "Roche." The hemoglobin in each sample was determined electrophotometrically according to Evelyn.¹⁷ In addition the iron content of the blood was determined following

Walker's¹⁸ modification of Wong's method. The hemoglobin was calculated on the basis of 0.336 per cent iron. The same 25 samples were also used for hemoglobin determinations in the Sica hemometer. The results of five to ten readings with each sample were averaged. Table I contains the synopsis of the results.

The average of the readings on the scale in the 25 blood samples was 92.07. The average for the oxyhemoglobin content photoelectrometrically measured, according to Evelyn, was 13.48 Gm. per 100 c.c. From these two figures was calculated that 100 parts on the scale of this particular instrument (A) equal 14.64 Gm. of hemoglobin per 100 c.c. Using this correlation, the hemoglobin content for each of the 25 samples was calculated from the respective Sica readings. The results are shown in Table I and can be compared with the respective figures from the photoelectrical readings and the iron determinations.

TABLE II

COMPARISON BETWEEN TWO SICCA HEMOMETERS (A AND B)
A Standardized by the Author; B Standardized by the Manufacturers

			25	14.6	14.4

TESTING OF MANUFACTURERS' STANDARDIZATION

The second Sica hemometer (B) was standardized by the manufacturers in Denmark in the manner commonly used there (in cooperation with Professor A. Krogh's Zoofysiologisk Laboratorium) on the basis of 100 parts of the scale equal 18.5 volume per cent of oxygen (Haldane); 18.5 volumes per cent of oxygen correspond to 13.85 Gm. of hemoglobin per 100 c.c. Thus the latter is at the same time the standardized hemoglobin value for 100 parts on the scale. In other words, one part on the scale means a little less hemoglobin with the instrument B than with the instrument A. A total of 25 other human blood samples were read in the two Sica hemometers. The same wedge chamber filled with the prepared blood was placed first in one instrument, and after the readings were taken (usually 5 to 10) placed in the other one. The order of the use of the two hemometers was alternating, thus also controlling any influence of time. The readings for each instrument were multiplied by their respective factors (0.1464 for A and 0.1385 for B). Table II shows the results obtained.

The hemoglobin content of the samples varied from about 8.7 to about 16.0 grams per cubic centimeter. The average of the values for the 25 blood samples

obtained with the two instruments is 13.1 and 13.2 Gm. per 100 c.c. In the individual results there is also a good agreement between the two instruments. The deviation is less than 1 per cent in 19 of the 25 cases, and never exceeds 2 per cent of the average reading.

The low dispersion for individual readings was also proved in the following manner: In 50 determinations with the Sieca hemometer in which ten readings had been taken for each sample, the average of the first three (R_3) and of the ten readings (R_{10}) was compared. In 48 of the 50 cases the per cent deviation of the two averages: $\frac{\pm (R_3 - R_{10})}{R_{10}} \cdot 100$ was not greater than 2; in the remaining 2 cases the deviation was 2.5 and 3.5 per cent, respectively. This means that by taking the average of three readings with the same specimen one can be certain of having a result correct for all practical purposes.

INTERCHANGEABILITY OF PARTS

One of the most important claims for the Sieca hemometer is that all spare parts are supposed to be interchangeable without restandardization. The parts of the wedge chamber evidently are the most vulnerable elements of the instrument in practical use. Three different base plates equipped with three different wedges were filled with blood from one sample. The readings were taken in the same instrument. The hemoglobin values obtained for the three wedge chambers were: 10.54; 10.64, and 10.45 Gm. per 100 c.c., respectively. This means a deviation of less than 1 per cent from the average.

Table III gives the average results of low hemoglobin values in four cases, two of them artificial dilutions, and two cases of pernicious anemia. The data obtained with wedge "2" in the Sieca are compared with those obtained with Evelyn's photoelectric method.

TABLE III

LOW HEMOGLOBIN VALUES DETERMINED WITH SIECA AND PHOTOELECTRICALLY

SAMPLE	SIECA HEMOMETER WEDGE "2" GM. HB./100 C.C.	PHOTOELECTRIC METHOD EVELYN GM. HB./100 C.C.
Diluted blood I + 0.9 per cent NaCl	5.33	5.41
Diluted blood II + 0.9 per cent NaCl	3.84	3.92
Pernicious anemia; Case P.	5.33	5.30
Pernicious anemia; Case C.	5.36	5.44

The photoelectric oxyhemoglobin determination (Evelyn) and the results obtained with the Sieca instrument, as a rule, were in very close agreement for the low as well as for the normal hemoglobin concentrations. In this connection it is of particular interest that, according to personal information by Dr. H. Hesse, a large series of hemoglobin estimations carried out in Montreal, Canada, with the Sieca instrument and with Van Slyke's method of determination the oxygen capacity never showed deviation exceeding 3 per cent.

SUMMARY

In my opinion some advantages of the new type of hemoglobinometer are:

(1) The use of undiluted blood eliminates the sources of error involved in diluting. The handling of the Sieca hemometer is very simple and needs no particular training.

(2) The use for colorimetry of acid hematin, repeatedly criticized in earlier work, is abandoned in favor of the color of reduced blood. The latter is stable and independent of time, the errors due to inadequate time for reading being eliminated.

(3) The use of constant glass standard and constant electric light in connection with correct filters allows observations with great optical contrast, eliminates the effects of voltage variations and plasma color (icteric blood), and decreases the personal equation to a minimum.

(4) The dispersion of repeated readings with the same or with different Sieca hemometers is small, i.e., the reproducibility is particularly good.

(5) Spare parts can be used without new standardization.

I gratefully acknowledge the assistance of the Ella Sachs Plotz Foundation in furtherance of my work in the field of hemoglobin determination.

THE MEASUREMENT OF CELL VOLUME OF BLOOD BY THE EVANS BLUE DYE METHOD*

ALFRED T. SHOHL, M.D., AND THOMAS H. HUNTER, M.D.
BOSTON, MASS.

THE hematocrit method for the determination of the cell volume in blood, as developed by Wintrobe,¹ Guest,² and others, has been of great service in both physiologic and clinical studies. It has the advantage of being simple and direct, and further, it gives separate readings for erythrocytes and leucocytes. It requires approximately 1 c.c. of blood. Careful studies of this method by Ponder³ and Hirota⁴ have shown, however, that it is not without its difficulties. The values obtained at 3,000 r.p.m. for thirty minutes, which is the condition commonly used, are arbitrary values, but, Ponder states, are correct ± 5 per cent. It is generally accepted that the error is within 2 or 3 per cent. Low speed and short duration of centrifugation result in a large volume of packed cells. Centrifugation at higher speeds or for longer times causes the volume of packed cells to become smaller to the point where fluid is squeezed out of the cells by centrifugal force. Moreover, various bloods do not attain the same equilibrium at the same time or speed of centrifugation.

A method for determination of cell volume, called the cell opacity method, has recently been described.⁵ This method depends upon the obstruction to light, of 660 $m\mu$, by a suspension of blood in citrate solution. The amount of light transmitted actuates a photoelectric cell, and the intensity of the current is measured by a galvanometer in a photoelectric colorimeter. An empirical correlation between this reading and the cell volume obtained by the hematocrit method is made. The method uses only 10 or 20 c. mm. of blood and requires only a few seconds to carry out. The values on relatively normal bloods agree within 2 or 3 per cent with those obtained by the hematocrit method.

To obviate the difficulties of the hematocrit method and to serve as a standard of reference, Ponder⁶ suggested the use of a colorimetric method based upon the addition of a solution of hemoglobin in plasma to whole blood from the same individual. The hemoglobin concentration of the plasma is determined before and after the addition, and the volume of the cells is thus calculated. The technical difficulties of this method in our hands have been considerable. It is open to the further objection that about 35 c.c. of blood are required for each determination. Further, what Ponder calls a solution of hemoglobin really contains all the soluble parts of the cell, high in potassium and

*From the Department of Pediatrics, Harvard Medical School, and the Infants' Hospital and the Children's Hospital, Boston.
Received for publication, April 17, 1941.

phosphate, obtained by freezing and lysis, and perhaps some cellular detritus. Practically, the effect of these substances on osmotic pressure is greatly reduced because the hemoglobin solution is diluted 1:15.

The method reported here is a colorimetric method which we think is free from these objections. The principle of the method is as follows: A known amount of blood is mixed with a given amount of the dye, Evans blue, also called T-1824. The concentration of the dye in the plasma is determined colorimetrically with a photoelectric colorimeter. Because the dye is contained wholly within the plasma, the volume of the plasma is determined by this measurement; from this the relative amount of the plasma in whole blood is calculated as per cent, and the cell volume is obtained by difference. The method is more laborious than the hematocrit method or the cell opacity method. It is offered primarily as a standard of reference rather than as a clinical method, although it may be so used.

PROCEDURE

Evans blue (Merek) is dried at 110° C. and made up into solution with distilled water so that it contains 400 to 800 mg. of dye per liter. One half to 1 c.c. of this solution (containing 400 μ g. of dye) is placed in a test tube of 3 to 4 c.c. capacity and evaporated to dryness at 70° C.

A measured amount of blood obtained by venepuncture is placed in a tube coated with a calculated amount of dried oxalate (60 per cent ammonium oxalate and 40 per cent potassium oxalate) or heparin to give a final concentration of 0.2 per cent oxalate or 2.0 to 2.5 units of heparin per cubic centimeter of blood. An aliquot is centrifuged. One cubic centimeter of plasma is placed in a tube containing the dye as described above (or a smaller volume but in the same proportion to the dye). The tube is shaken and the dye readily goes into solution. Of the plasma containing dye 0.1 c.c. is removed and placed in 9.9 c.c. of physiologic saline solution (0.85 per cent of sodium chloride) in a tube standardized for use in the photoelectric colorimeter. (The saline prevents precipitation of protein which would occur if the plasma were diluted with water.) Of the dye-free plasma 0.1 c.c. is placed in a similar colorimeter tube containing 9.9 c.c. of saline solution to serve as a "blank." The pipettes to be used for this purpose are those described by Levy.⁷ These pipettes are calibrated "to contain," and automatically deliver the required volume, because they are constricted at the upper mark to a hairline diameter. The sample of plasma is delivered into the pipette washed with the saline solution.

A suitable photoelectric colorimeter, such as the Evelyn or the Klett-Summerson colorimeter, is arranged for use with a filter transmitting light at approximately 620 $m\mu$. This filter was selected as most suitable by Gibson and Evelyn¹¹ after a study of the absorption curve of the dye. The blank is inserted and the machine is adjusted to read at 100 on the Evelyn or at 0 on the Klett-Summerson colorimeter. The dye tube is then inserted and the reading made. The dye has a very intense color, and the optimal concentrations for accurate reading in the Evelyn or Klett-Summerson colorimeter are approximately 15 to 50 μ g. of Evans blue in a volume of 10 c.c. By adding varying amounts of

saline or plasma to the dye different readings are obtained which establish a straight line, as shown in Fig. 1.

The procedure for analysis of blood is similar to the quantitation of the dye in plasma. One, 2, or 3 c.e. of oxalated or heparinized blood are placed in a tube containing 400 μ g. of Evans blue. (If 1 c.e. of blood is used, either half the amount of dye or twice the amount of diluent should be used.) The tube is stoppered and shaken until the dye is completely dissolved. The tube is then centrifuged at moderate speed, 1,500 r.p.m., for fifteen minutes. An aliquot of 0.1 c.e. of the supernatant plasma is added to 9.9 c.e. of saline in a colorimeter tube. The same plasma blank as above is used to determine the point of zero concentration of dye. The concentration of dye in the sample analyzed is obtained from the galvanometer reading by the use of the curve in Fig. 1. The cell volume is then calculated as follows:

A = amount of dye used; μ g.

Z = concentration of dye determined in supernatant plasma;
 μ g. per cubic centimeter.

S = volume of blood used; c.e.

P.V. = plasma volume; per cent of whole blood.

C.V. = cell volume; per cent of whole blood.

$$\frac{A}{Z \times S} \times 100 = \text{P.V.}; 100 - \text{P.V.} = \text{C.V.}$$

Example: A = 400; Z = 370; S = 2.

$$\frac{400}{370 \times 2} \times 100 = 54.0 = \text{P.V.}; 100 - 54.0 = 46.0 = \text{C.V.}$$

It is obvious that this method gives a measure of the volume of plasma in a given amount of blood, and hence the cell volume obtained by subtraction includes all the fixed elements in the blood, and not in the erythrocytes alone.

The first step in applying this method is for the operator to determine that he can make adequate recovery of the dye in water or saline, and then in plasma, and thus establish his curve. This curve can be used without making a plasma determination for each blood analyzed so long as the same lot of dye is used.

No attempt was made to handle the blood without loss of carbon dioxide or exposure to the air, but it was treated with reasonable care. It was kept in tubes nearly filled and always stoppered, and was analyzed within one hour after venepuncture. All the glassware was carefully calibrated. It was washed in cleaning solution before each use, and then repeatedly washed with distilled water. If the precaution of using cleaning solution is not observed, the blue dye will adhere to the glass.

Five cubic centimeters of blood are adequate for this determination in duplicate; two 1.0 c.e. samples are measured into tubes containing dye, the remainder is centrifuged to obtain plasma for the blank and for the determination of the concentration of dye in the plasma to check against the curve. If the centrifuging is done in a hematocrit tube, the cell volume may be read before the plasma is removed, and thus a comparison made without extra blood being required.

EXPERIMENTAL RESULTS

We wish to compare the results of simultaneous determinations of cell volume on the same blood by the hematocrit method, the cell opacity method, and the colorimetric Evans blue method. We used 15 c.c. of blood to enable us to make observations on known concentrations of dye in plasma on each blood, and quadruplicate determinations of cell volume employing aliquots of 1, 2, or 3 c.c. of blood. The results of the 16 consecutive determinations most recently made are given in Table I.

*A standard value of 0.5 volumes per 100 volumes of blood was added to the red blood cell volume.

†This case has been omitted from all averages for two reasons. First, it is a case of microcytic anemia, in which (as was stated in the original paper) the values obtained by the cell opacity method are too low. Second, because the total cells are only $\frac{2}{3}$ of the average for total cells, the difference between the hematocrit and the dye method should be only $\frac{2}{3}$ of the average difference between the two methods. These variations are shown quantitatively in this case.

In column 1 are given the values obtained by the hematocrit method for the volume of the red blood cells only. Hematocrit tubes were capped and spun at 3,200 r.p.m. for thirty minutes, usually in duplicate. The speed of centrifugation was checked frequently. The volumes were read ± 0.2 to 0.3 per cent of the whole blood. The readings were in agreement by the independent observations of the two observers.

In column 2 are given the cell volumes as measured by the cell opacity method. These values were determined from the line given in Fig. 2, which was established as follows: The average of the volumes of red blood cells only, obtained by the hematocrit method, was plotted against the arithmetical average of the galvanometer readings for this series of determinations. The galvanom-

eter reading for plasma alone (0 cell volume) is 98. The two points were connected by a straight line.

The results of the hematocrit method and the cell opacity method are compared in column 5. With the exception of the first case the volumes by the cell opacity method correlate with those of the hematocrit method well within the limits of the agreement originally claimed for the cell opacity method.

Fig. 1.—Concentration of Evans blue in plasma. This curve was made from known concentration of the dye in plasma. For each determination 0.1 c.c. of plasma was diluted to 10 c.c. with 0.85 per cent sodium chloride solution.

In column 3 are given the total cell volumes obtained by the hematocrit method. A constant value of 0.5 volumes per 100 volumes of blood was added to the red blood cell volume, as given in column 1 to obtain the total cell volume. We considered this value more accurate than actual reading of the volume of the buffy coat. We selected 0.5 rather than the more widely accepted 0.6, so that the error, if any, should make the total too small rather than too large.

In column 4 are given the cell volumes obtained by the colorimetric Evans blue method, as described under Procedure. The values were calculated from the line given in Fig. 1.

The values given in columns 3 and 4 are compared in column 6. The volumes obtained by the dye method never exceeded or even equaled those obtained by the hematocrit method, and averaged 2.1 volumes (4.5 per cent) less than the hematocrit values. Four aliquots of the same blood analyzed by the

Evans blue method have always yielded values within 1 per cent of one another (that is, 0.5 volumes of cells per 100 volumes of blood). Inasmuch as duplicate hematocrit determinations always agreed within our error of reading, and inasmuch as the absolute accuracy and causes for variation in the hematocrit method are unknown, it is impossible for us to state the difference between the two methods in accurate statistical terms. Approximate analysis shows that this value is more than five times the probable error of the difference ($\sqrt{\text{sum of the squares of the probable errors}}$) and therefore the difference is statistically highly significant. Even if the buffy coat were not taken into account the difference would still be significant.

Fig. 2.—Cell volume by the cell opacity method. X = the average of the determinations in this series, which were made with 20 c.mm. of blood suspended in 10 c.c. of citrate solution and read in an Evelyn photoelectric colorimeter.

Gregersen and Schiro⁸ found a difference of 4.2 per cent between the recovery of the dye added to whole blood and that recovered in the supernatant plasma following centrifugation. This value is in excellent agreement with the difference we found between the values for cell volume obtained by the dye method and by the hematocrit method, namely, 4.5 per cent.

It seems reasonable that the lower volumes obtained by the colorimetric method represent a truer value than that obtained by the hematocrit method. The red blood cells, whether they are biconcave disks, or cup-shaped, or spheroid, could hardly be packed so tightly that there would be no plasma between them. This deduction is subject to experimental verification by seeking for dye in the packed cells, which would prove the presence of plasma between them.

We added 5 c.c. of oxalated whole blood to a tube containing 4 mg. of Evans blue. This was thoroughly agitated until the dye was completely dissolved, and 4 c.c. of the blood were transferred to a tube with a constriction slightly below the 2 c.c. level. This tube and a hematocrit tube were centrifuged at 3,200 r.p.m. for thirty minutes. The packed cells extended above the constriction. The tube was scratched with a file at this point and broken off. The sticky packed cells were then transferred by repeated washings into 15 c.c. of physiologic saline solution. This was centrifuged and 10 c.c. of the clear supernatant solution, tinged blue, were removed and measured for concentration of Evans

blue. The volume of cells removed was determined by measuring the capacity of the tube which had contained them. From the volume of cells used, the concentration of dye, and the known cell volume, it was calculated that about 2 per cent of the dye was distributed within the space occupied by the packed cells. A similar procedure was used by Gregersen and Schiro⁸ when they washed the cell residue with isotonic saline or dye-free plasma and recovered 3.9 per cent of the dye.

Under physiologic conditions leucocytes occupy such a small percentage of the total volume of cells that they may be neglected for most clinical purposes. By the colorimetric method the total plasma is determined, and hence the total cells. Whether the packed leucocytes contained plasma in the same proportion as the packed erythrocytes may under some conditions be an important problem. If pure white blood cells could be obtained readily, the problem could be attacked in the manner just described for red blood cells. This we have been unable to do, but we made orientation experiments. Forty to 45 c.c. of blood were centrifuged in two tubes specially constructed so that the white blood cells and platelets were contained in a constricted column. The buffy coat, admixed with less than one-half its volume of red blood cells, was removed and suspended in its own plasma. Aliquots of this mixture were taken for measurement of cell volume by the hematocrit, the colorimetric, and the cell opacity methods. The values obtained by the hematocrit method were 3.0 and 3.3 per cent for the erythrocytes and buffy coat, respectively, a total cell volume of 6.3 per cent. By the Evans blue method the cell volume was 5.0 to 5.5 per cent, and by the cell opacity method it was 3.5 per cent. As in the other experiments reported the cell volume determined by the dye method was less than that given by the hematocrit method. The determination is not sufficiently accurate to state whether more or less dye is included in the packed white cells and platelets than in the packed red blood cells. It is beyond doubt, however, that the white blood cells occupy volume as recorded by the blue dye method. This experiment also confirms the previous observations made upon the blood of patients with leucemia, that the cell opacity method gives values little influenced by the white blood cells.

DISCUSSION

The behavior of Evans blue dye in blood has been exhaustively studied by Gregersen, Gibson, and their collaborators,⁸⁻¹¹ who have used it successfully in the determination of plasma volume in vivo. These investigators were so interested in the use of the dye for this purpose that they did not point out the applicability of their findings to the determination of the relative volumes of plasma and cells in whole blood.

We have made the assumption that Evans blue is contained wholly in the plasma and does not enter the cells. Gregersen and Schiro⁸ concluded that the dye is dissolved only in the plasma, combined with the serum protein, and that the red blood cells do not permit either penetration or absorption of the dye. In agreement with their observations we found, as detailed above, that dye contained in packed cells is readily transferred to saline solution. Further, although we used 1, 2, and 3 c.c. aliquots of blood with the same or different

amounts of dye, we have obtained the same cell volume calculated from all aliquots, within the experimental error. If the dye had been adsorbed on, or had penetrated into, the cells this finding would mean that, regardless of concentration, the same proportion of dye was held by the red blood cells, which is highly unlikely.

In determining cell volume by the hematocrit method the effort was made to have the speed of centrifugation greater than rather than less than the usual number of revolutions per minute, and thus to err on the conservative side. The larger volumes obtained by the hematocrit method cannot, therefore, be attributed to spinning the blood at too slow a speed.

The reason for making a new curve for the cell opacity method based on the present data instead of using the one previously published, was that the latter would be interpreted in terms of red blood cell volume as one or two volumes too great. The measurement of cell opacity is an independent physical measurement, and its relation to the hematocrit method is purely empirical. The absolute value for cell volume calculated from it, therefore, is theoretically not of prime importance; the main virtue of the method lies in the fact that the correlation between it and another method is close under a given set of conditions. The original data consisted of observations on a large number of children, some of which were above and some below the line adopted. In this case we have used few individuals, all adults; mostly with high cell volumes, and it may be that we have accidentally selected individuals whose cell opacity readings fell below the original line. All the methods in this study were carried out with the greatest precision. In the former study only clinical exactness was attempted. Therefore, especially for high cell volumes, this curve is more accurate. The difference between this curve and the former one decreases as the cell volume becomes smaller.

In this series of observations we have been unable to detect any consistent difference between values whether 0.2 per cent of oxalate or 1 mg. of heparin per cubic centimeter of blood was used as anticoagulant. Neither caused swelling nor shrinking of the cells sufficient to be demonstrated, even when aliquots of the same blood were compared.

Hemolysis was not visible in any samples of blood studied. If any was present, it was probably too small to affect the cell volume significantly. In any event it was the same in the aliquots compared by the three methods. In their studies of blood volume in vivo by the use of Evans blue, Gibson and Evelyn¹¹ found it necessary to analyze successive samples of blood in which the degree of hemolysis varied. They have shown how to correct adequately for this complicating factor. Such correction does not apply to the present study, for the dye-free plasma is used for the blank, and any interference due to hemolysis is thus eliminated. In Gibson and Evelyn's studies it was necessary to use undiluted plasma in order to obtain a concentration of dye sufficient to read in the colorimeter. Under our experimental conditions any amount of dye up to the saturation point may be used, thus eliminating the necessity for microtechnique. We used sufficient dye so that the color could be read to maximum

advantage when the plasma was diluted to 100 times its volume. This also reduced to a minimum any difficulties which might be due to any interfering substances in the plasma.

We are at a loss to account for the fact that Ponder's findings are not in agreement with ours concerning the relationship between colorimetric and hematocrit methods. He presented a table⁷ which he stated "is representative of the results of many experiments." In this he compared the cell volumes given by his colorimetric hemoglobin method with those obtained by centrifuging the blood at various speeds and for various times. Two samples of blood analyzed by both methods gave values for the volume of a single cell of 85 and 78 μ^3 by the hematocrit method (spun at 4,000 r.p.m.), and 83 and 82 μ^3 by the colorimetric method, respectively. Thus each method gave values both higher and lower than the other. He did not include the buffy coat.* In our experience the colorimetric hemoglobin method yielded results more variable than did the Evans blue method. However, the hemoglobin method, as well as the Evans blue method, gave a lower average for cell volume than the hematocrit method.

SUMMARY

A colorimetric method is presented for the determination of the relative volume of the plasma and cells in blood by the use of the Evans blue dye. The error is less than 1 per cent.

By this method the total cell volume averages approximately 4.5 per cent (2.1 volumes per 100 volumes of blood) less than that obtained by the hematocrit method. This discrepancy is probably accounted for by the plasma which lies between the packed cells.

PLASMA ALBUMIN, GLOBULIN, AND FIBRINOGEN IN HEALTHY INDIVIDUALS FROM BIRTH TO ADULT LIFE*

I. A SYSTEM OF MICROANALYSIS

ROBERT M. HILL, PH.D., AND VIRGINIA TREVORROW, PH.D.
DENVER, COLO.

FOR the past eight years we have been gathering data on the levels of the plasma proteins in healthy infants and children. In this work it is frequently necessary to use very small samples of plasma. To accomplish our task we have adapted existing analytical methods to microprocedures and have added certain techniques, all of which taken together have developed into a system of analysis for the plasma proteins that has become routine in our laboratory.

In view of the relative dependability of salting-out methods, we have based our separation of the plasma protein fractions on procedures similar to those of the "Howe technique."¹ With respect to the separation with sodium sulfate, we have found that this procedure may be carried out at room temperature and that, when filtration is used for the removal of the precipitated globulin, there is a loss of albumin seemingly due to adsorption by the filter paper. During the course of the present work, both of these findings have been reported by Robinson, Price, and Hogden,^{2, 3} and the latter one has been confirmed by Harris.⁴ In addition, we have found it possible to determine serum globulin, or plasma globulin plus fibrinogen, directly in samples which do not show a marked lipemia. The nitrogen content of the fractions is determined by means of a micro-Kjeldahl procedure. We have devised a distillation apparatus which may be easily and inexpensively constructed from ordinary laboratory glassware, and which has proved very satisfactory in the hands of many workers in this laboratory.

In this, as in any microanalytic work, the factor most essential to success is strict attention to detail. We are, therefore, presenting our method at some length, together with a critical analysis of the results obtained. In the near future we shall present the values obtained in our study of healthy individuals from birth to adulthood.

METHOD

A complete analysis consists of duplicate determinations of each of the following fractions: (1) total nitrogen, (2) nonprotein nitrogen, (3) fibrinogen, (4) albumin plus nonprotein nitrogen, and (5) globulin plus fibrinogen. For this, eight 0.1 c.c. samples of plasma are needed. In measuring the samples, 0.1 c.c. pipettes, which have been recalibrated, are used. The calibration is made

*From the Child Research Council and the Department of Biochemistry, University of Colorado School of Medicine, Denver.
Received for publication, May 19, 1941.

on the volume each pipette will contain. Throughout the procedure, all tubes are kept tightly stoppered to avoid errors due to evaporation.

Reagents:

- 10% sodium tungstate, nitrogen free
- $\frac{2}{3}$ N sulfuric acid, nitrogen free
- Sodium hydroxide-potassium dihydrogen phosphate buffer for fibrinogen and globulin precipitants:
- 10.05 Gm. of potassium dihydrogen phosphate
- 508.0 c.c. of 0.1 N sodium hydroxide
- Water to make 1 liter

According to Howe,⁵ this amount of potassium dihydrogen phosphate per liter would be equivalent to 6.98 Gm. of sodium sulfate for the precipitation of fibrinogen, or 7.76 Gm. of sodium sulfate for the precipitation of globulin.

Fibrinogen Precipitant:

- 104.6 Gm. of sodium sulfate (anhydrous)
- Buffer to make 1 liter

This solution has an effective precipitating strength of 104.6 Gm. plus 6.98 Gm., or 111.58 Gm. of sodium sulfate per liter. After dilution with plasma (0.1 c.c. of plasma to 1.9 c.c. of precipitant), the strength is 106.0 Gm. per liter.

Globulin Precipitant:

- 218.5 Gm. of sodium sulfate (anhydrous)
- Buffer to make 1 liter

The final effective strength of the globulin precipitant after dilution with plasma and correction for the buffer salts is 215.0 Gm. per liter.

Both the fibrinogen and globulin precipitants may be slightly hazy at first, and after a few days may develop a flocculent precipitate. The solutions with the precipitates may be used, provided that 5 c.c. samples are found to be free of nitrogen after digestion, distillation, and nesslerization. Because of the buffer present, the solutions cannot be directly nesslerized.

Digestion Mixture:

- | | |
|-----------------------------------|-----------|
| Concentrated sulfuric acid (C.P.) | 3 volumes |
| "Syrupy" phosphoric acid | 1 volume |

Hydrogen Peroxide, 30 per cent solution. Should not contain more than 0.025 mg. nitrogen per cubic centimeter.

Saturated Potassium Hydroxide.

Indicator:

- 1.250 Gm. of methyl red
- 0.825 Gm. of methylene blue
- 90 per cent ethyl alcohol to make 1 liter

The acidity of the indicator must be determined by titration with N/10 sodium hydroxide, so that the proper correction may be made in the final calculation.

Standard Sodium Hydroxide. A carbonate-free 0.1 N solution of sodium hydroxide is prepared and standardized against purified potassium acid phthalate in a concentration of 2 Gm. per 100 c.c.

Standard Sulfuric Acid. This solution should be free of ammonia, and for convenience, the normality should not be greater than that of the sodium hydroxide, since 1.0 c.c. of the solution is to be titrated with sodium hydroxide from a microburette of 1.0 c.c. capacity.

Nessler's Solution.

Stock Ammonium Sulfate, 1.0 mg. nitrogen per 1 c.c. in 5 per cent sulfuric acid.

Dilute Ammonium Sulfate, 0.04 mg. nitrogen per 1 c.c.

The solution is prepared by diluting 1 c.c. of the stock solution to 25 c.c. with water and is checked by Kjeldahl analysis of 10 c.c. portions.

*Heparin.** For plasma analysis we have used heparin as the anticoagulant.

PREPARATION OF THE SAMPLES

Total Nitrogen. One-tenth cubic centimeter of plasma is added to 1.0 c.c. of water in a 25 by 200 mm. pyrex test tube. The pipette is washed several times with the mixture and allowed to drain thoroughly. The final drop is blown out. One cubic centimeter of digestion mixture is added.

Nonprotein Nitrogen. One-tenth cubic centimeter of plasma is added to exactly 1.0 c.c. of water in a 15 c.c. pointed centrifuge tube. The pipette is washed with the mixture, drained, and the last drop is blown out. One-tenth cubic centimeter each of 10 per cent sodium tungstate and $\frac{2}{3}$ N sulfuric acid are added. The mixture is stirred with a small glass rod, care being taken not to spread the precipitate over the tube above the fluid level. This is centrifuged (fifteen minutes at about 1,800 r.p.m.), and the clear fluid is transferred by means of a capillary tube to a clean dry test tube. Great care must be taken to avoid including any particles of the precipitate during this transfer. An aliquot of 0.7 c.c. of this is placed in a 25 by 200 mm. pyrex test tube, and 1.0 c.c. of digestion mixture is added.

Fibrinogen. One-tenth cubic centimeter of plasma is added to exactly 1.90 c.c. of fibrinogen precipitant in a 15 c.c. tapered centrifuge tube, the pipette is washed three times with the solution and drained. In adding the plasma, the tip of the pipette is placed about $\frac{1}{4}$ inch under the surface of the precipitant and allowed to drain. The plasma rises from the tip to float on the surface, and the pipette is carefully washed three times with the clear underlying fluid. In the final washing, the pipette, filled with clear fluid, is withdrawn so that the tip rests against the tube just above the fluid. The pipette is allowed to drain while being rotated against the tube, thus washing back any particles adherent to its outer surface. The final drop is blown from the end of the pipette, and the contents of the tube are mixed by rotation and allowed to stand. After standing for three hours, the precipitated fibrinogen is centrifuged down to a compact, cohesive mass. This requires ten to fifteen minutes at about 1,800 r.p.m. The clear supernatant fluid is poured off, and the tube is inverted over filter paper to

*Heparin, obtained from the Connaught Laboratories, Toronto, containing 110 units per milligram has been found most satisfactory.

drain. One and nine-tenths to 2.0 c.c. of fibrinogen precipitant are added to the tube, and the contents are mixed, centrifuged, decanted, and drained. The fibrinogen pellet is transferred quantitatively to a 25 by 200 mm. pyrex test tube by means of 2 to 5 c.c. of water. One cubic centimeter of digestion mixture is added.

In precipitating fibrinogen it was found that, although the protein had flocculated within three hours, longer standing tended to yield slightly higher values. A series of fibrinogen determinations were done on 83 samples of plasma in which two fractions of each sample were allowed to stand three hours, after which the supernatant fluids were removed and allowed to stand for twenty-one hours longer. Another set of duplicates was allowed to stand for twenty-four hours before being centrifuged. The mean value for those standing for three hours was 0.188 per cent fibrinogen, and for twenty-four hours, 0.204 per cent. In 8 of the plasma samples the increase after three hours was greater than 0.04 per cent, an amount easily detected; yet in no case was there any further salting-out of protein in the supernatant fluids removed after three hours, as would be expected if the increment were due to continued precipitation of the fibrinogen. Consequently, it was deemed possible that the increase with longer standing may be due to adsorption of other proteins upon the already precipitated fibrinogen. In a series of analyses of 5 samples of plasma, the fibrinogen was determined after intervals of one hour, two, three, six, nine, twelve, and twenty-four hours' standing. In each case there was a sharp rise to the three-hour sample, after which the curve leveled. It was, therefore, decided to standardize the procedure, using this interval of time for the fibrinogen precipitation.

Albumin Plus Nonprotein Nitrogen. One-tenth cubic centimeter of plasma is added to exactly 1.90 c.c. of globulin precipitant in a 15 c.c. tapered pyrex centrifuge tube. The addition is made in the same manner as that used for fibrinogen, and the contents of the tube are mixed and allowed to stand for three hours at room temperature. We have found that longer standing, up to twenty-four hours, does not alter the amount of globulin precipitated. The tubes are then centrifuged for forty-five to sixty minutes at 2,600 r.p.m. In all cases studied, except those showing a marked lipemia, this centrifugation has been sufficient to remove the globulin as a small, fairly compact mass, leaving a crystal-clear supernatant albumin solution. This clear solution is transferred by means of a capillary tube with bulb attachment to a clean, dry test tube. One cubic centimeter of the albumin solution is pipetted into a 25 by 200 mm. pyrex test tube, and to it 1 c.c. of digestion mixture is added. The precipitate is saved for globulin analysis.

In those cases in which the plasma shows an extreme lipemia (in our work, infants, bled one to two hours after feeding), it is difficult or impossible to remove the globulin by centrifugation. In a few such instances, the precipitate rose to the top on prolonged centrifugation, and the clear supernatant solution was removed for albumin determination. More often, however, the precipitate failed to separate completely, and it was necessary to remove it by filtration. A small (1 to 1.5 cm.) funnel was fitted with a 2.5 cm. filter paper (nitrogen free),*

*The filter paper must be tested for soluble nitrogen.

by moistening with 95 per cent ethyl alcohol and drying in a current of air. The funnel was then placed in a test tube supported inside a large, straight-walled desiccator containing globulin precipitant to a depth of one inch. The desiccator should be covered during filtration, allowing the air to maintain water equilibrium with the globulin precipitant and thus prevent evaporation from the protein solution. The solution should be repeatedly filtered through the same paper until the filtrate is clear. One cubic centimeter of filtrate is used for albumin analysis.

In cases where the solution is filtered through paper, a correction is necessary because of the albumin adsorbed on the paper. This correction is determined by running a series of albumin analyses in which the values obtained by filtration and centrifugation are compared. In a series of 50 such determinations in our work, the filtrate albumin was lower than that in the centrifuged supernatant solution by 4 per cent of the amount present in the latter sample. This figure would probably vary with the size and quality of filter paper used.* Robinson, Price, and Hogden³ have obviated the need for this correction by first saturating the paper with albumin, then filtering a second portion of the solution through the same paper. This method was not practical in our work, since only a small amount of plasma was available for complete analysis.

Centrifugation and filtration are carried out at room temperature since, in agreement with the work of Robinson, Price, and Hogden,² we have found no difference between these results and those obtained when the precipitation and removal of globulin are done at 37° C. Our work was done at 25° to 35° C. Although no determinations were completed at temperatures below this point, it seems likely that the results at 20° C. would be comparable, since sodium sulfate does not crystallize from the solution at this temperature.

Globulin Plus Fibrinogen. The precipitate remaining after removal of the albumin solution (by centrifugation) is washed with 2.0 c.c. of globulin precipitant. For this washing, one drop of the fluid is added, and the precipitate is first broken up and suspended in this small volume by gently tapping the tube, then the remainder of the 2.0 c.c. is added. To the mixture 0.1 c.c. of water is added. This amount of water dilutes the precipitant to approximately the same concentration of sodium sulfate which was used originally; however, its chief function is to lower slightly the specific gravity of the medium and to insure removal of the precipitate on subsequent centrifugation. With clear or slightly lipemic plasma samples the 0.1 c.c. of water is unnecessary, since the precipitate may be removed by centrifugation and the error caused by the higher concentration of sodium sulfate is negligible. With a moderate lipemia the globulin remains suspended upon centrifugation unless this water has been added to the washing fluid. The above mixture is centrifuged for forty-five minutes at 2,600 r.p.m., and the fluid is removed and discarded. The precipitate is washed a second time, centrifuged, and the washing fluid is discarded.

The precipitate of globulin and fibrinogen is now transferred to a 25 by 200 mm. pyrex test tube. Approximately 1 c.c. of water is added to the precipitate

*We have used E. and D. No. 613, smooth finish filter paper.

and allowed to stand for ten minutes or longer. This loosens the pellet so that it can be transferred as a whole to the digestion tube. The centrifuge tube is washed with three or more successive small portions of water. One cubic centimeter of digestion mixture is added to the precipitate plus washings, and the tube is heated in a boiling water bath for thirty minutes, or until it begins to show discoloration. This preliminary heating avoids excessive foaming in the subsequent digestion.

In cases where the globulin is originally removed by filtration, it is discarded and the amount present is determined by difference.

DIGESTION OF SAMPLES

Each of the tubes prepared as outlined above is treated in the following manner: Add 2 or 3 glass beads. Heat with a microburner until dense fumes of sulfur trioxide are given off. Cool. Add 2 drops of 30 per cent hydrogen peroxide, and heat as before. Cool. Add 1 drop of the hydrogen peroxide and again heat until fumes are given off. Cool, and repeat, again using 1 drop of hydrogen peroxide. Cool well and add about 10 c.c. of water.

DISTILLATION OF NITROGEN

Ammonia from each of the samples of albumin, globulin plus fibrinogen, and total nitrogen is distilled into exactly 1.0 c.c. of standardized N/10 sulfuric acid contained in a test tube of 20 to 30 c.c. capacity. The nonprotein and fibrinogen nitrogens are distilled into 1.0 c.c. of the acid in a Peebles-Lewis colorimeter tube.⁶ If the Peebles-Lewis colorimeter is not used, the ammonia can be distilled into a graduated test tube and an appropriate aliquot taken for nesslerization.

Fig. 1 is a diagram of the completely assembled distillation apparatus, which is similar to that of Pregl as modified by Goebel.⁷ The only important new feature is the reservoir (I) of redistilled water attached to tube B through a slightly constricted opening, as indicated in Fig. 1. We also use a current of air washed with 10 per cent sodium hydroxide and 10 per cent sulfuric acid rather than the steam distillation employed by Goebel. The inverted flask, III, serves as a trap and equalizes the air current through the apparatus. The entire apparatus may be easily assembled from ordinary laboratory glassware, and is mounted upon a single ring stand. Especial care should be taken to insure a close fit of the stopper *a* to the digestion tubes (IV) and to the tubes A and B. Any space which may fill with condensed steam serves potentially as a trap to retain ammonia. We have used a quality of stopper designated as "sulfur-free, translucent, floating stock," and have replaced the stopper at the first sign of spreading around tubes A and B, or of hardening of the rubber. Tube B has a 2 to 3 mm. hole in its upper surface about 2 cm. from the lower end, and just below stopper *a*. This allows a free passage of air and steam through the apparatus at the same time that condensed steam is draining back from B to the test tube IV.

The distillation procedure is as follows: Clamp the digestion tube (IV) in position. Place the receiver (V) containing 1.0 c.c. of acid in the beaker VI and put it into position as shown in Fig. 1. The beaker is half filled with cold water.

Fill the burette *II* by means of clamp *1*. Start the current of air with clamp *4* open; then by slowly closing *4*, the air is directed as a moderately rapid stream through the apparatus. With the air flowing, slowly add 4.0 c.c. of the saturated potassium hydroxide to tube *IV* by opening clamp *2*. After about one minute begin heating tube *IV* with a microburner, and continue heating and aeration until steam begins to enter the receiver fluid as determined by the crackling

Fig. 1.

noise produced (about two minutes). At this point, remove the flame and open clamp *4*, stopping the flow of air. Lower the receiver until tube *C* is above the fluid level. If necessary, blow out tube *C* by momentarily placing a finger over the rubber tube below clamp *4*, but do not run a large amount of air through the apparatus. Wash back the ascending arm (tube *B*) of the distillation apparatus with water from *I* by opening clamp *3*. Cooling within the apparatus will suck the water back into *IV*. Now raise the receiver, start the air, and heat until steam again reaches the acid. Stop the distillation, and wash as before. Repeat this procedure once more. After the final washing of tube *B*, with the

receiver still in its lowered position, start the air and admit a small amount of water at clamp 3. This will be blown through C into the receiver. Again heat tube IV, and continue aeration and boiling for about two minutes. The total volume of the distillate and washings should be about 8 c.c.

DETERMINATION OF AMMONIA IN THE DISTILLATES

Total-, Albumin-, and Globulin-Plus Fibrinogen-Nitrogen. To the distillate add 3 drops of indicator and titrate with standard sodium hydroxide until no further change of color is produced by the addition of more alkali. We use a modified Rehberg⁸ burette of 1.0 c.c. capacity, calibrated to 0.01 c.c. The reading is estimated to 0.001 c.c.

Nonprotein Nitrogen and Fibrinogen. The distillate in the Peebles-Lewis colorimeter tube is made up to 8.0 c.c. with water. To this are added 2.0 c.c. of Nessler's solution, and comparison is made with standards prepared at the same time as the unknown solution. Two standards are prepared as follows:

	I	II
Ammonium sulfate	1.0 c.c.	2.0 c.c.
(0.04 mg. nitrogen per cubic centimeter)		
Water to make	16.0 c.c.	16.0 c.c.
Nessler's solution	4.0 c.c.	4.0 c.c.

In making the color comparison, the unknown is left at a volume of 10 c.c., and the standard is adjusted to match it. The volume required is recorded.

With extremely high values for nonprotein or fibrinogen nitrogen, it is necessary to use an aliquot of the distillate, therefore, it is advisable to add Nessler's solution to only one of each pair of duplicates until the approximate ammonia concentration has been determined.

DETERMINATION OF BLANKS

Two cubic centimeters of digestion mixture and 8 drops of 30 per cent hydrogen peroxide in a 25 by 200 mm. pyrex test tube are heated to dense fumes of sulfur trioxide. This is cooled well, and 10 c.c. of water are slowly added. Duplicate samples are distilled for titration and for nesslerization, using 8 c.c. of saturated potassium hydroxide. The distillate for nesslerization is made up to 8 c.c., and 2 c.c. of Nessler's solution are added. This is compared with a standard containing 1 c.c. of ammonium sulfate, 23 c.c. of water, and 6 c.c. of Nessler's solution. The value found is divided by 2 to obtain the correction blank.

We have found the ammonia blank for these reagents to equal the acid blank of 2 to 4 drops of indicator, and for convenience we have adjusted the amount of indicator between these limits to cancel the ammonia blank in the samples for titration.

CALCULATION OF RESULTS

Nonprotein Nitrogen:

$$\frac{\text{Reading of standard}}{20} \times \text{mg. nitrogen in standard} = \text{mg. nitrogen in distillate.}$$

$$\frac{(\text{Mg. nitrogen in distillate} - \text{blank}) \times 1.3 \times 100}{\text{Volume of plasma sample} \times 0.7} = \text{mg. nitrogen per 100 c.c.}$$

Fibrinogen. The calculation is similar to that for nonprotein nitrogen. The value for milligrams nitrogen per 100 c.c. is converted to milligrams protein by multiplying by the factor 6.25; this is divided by 1,000 in order to express the final result in terms of grams.

Total Protein:

$$\begin{aligned} &\text{c.c. N/10 sulfuric acid + indicator blank} - \text{c.c. N/10 sodium hydroxide} - \text{ammonia} \\ &\quad \text{blank} = \text{c.c. N/10 ammonia distilled.} \\ &\text{c.c. N/10 ammonia} \times 1.4 \times 100 \\ &\quad \text{Volume of plasma sample} = \text{mg. total nitrogen per 100 c.c.} \\ &\frac{\text{Mg. total nitrogen} - \text{nonprotein nitrogen}}{1,000} \times 6.25 = \text{Gm. protein per 100 c.c.} \end{aligned}$$

Albumin. The calculation is similar to that for total protein, except that the value for milligrams nitrogen must be multiplied by 2 since an aliquot equal to one-half of the albumin solution was used.

Globulin Plus Fibrinogen. The calculation is similar to that for total protein, except that no correction is made for nonprotein nitrogen.

REPRODUCIBILITY OF RESULTS AND A CONSIDERATION OF THE
"SALTING-OUT" PROCEDURE

The accuracy of the Kjeldahl procedure may be judged from the results obtained in a series of 24 analyses of the total nitrogen in 0.1 c.c. fractions of a single sample of plasma. The 24 determinations gave a mean value of 1.187 mg. nitrogen, with a standard deviation of 0.011 mg. nitrogen. The highest value obtained, 1.220 mg., is 0.033 mg., or three standard deviations above the mean, and the lowest value, 1.168 mg., is 0.019 mg., or about two standard deviations below the mean. The results obtained on a series of 100 consecutive complete determinations were also analyzed statistically.⁹ The standard deviation and standard error of the difference between duplicates for each fraction are given in Table I.

TABLE I
ACCURACY OF THE METHOD

NITROGEN FRACTION	STANDARD DEVIATION OF DIFFERENCE	STANDARD ERROR OF DIFFERENCE
	Gm. protein per 100 c.c.	Gm. protein per 100 c.c.
Total protein	0.072	0.101
Albumin	0.077	0.109
Globulin + fibrinogen	0.035	0.049
Fibrinogen	0.0087	0.0123
Nonprotein nitrogen	Mg. nitrogen per 100 c.c.	Mg. nitrogen per 100 c.c.
	1.123	1.742

In routine analyses a value obtained in a single determination should be within two standard deviations of the true value in 95 per cent of the cases. When duplicates are run, the results should differ by not more than two standard errors in 95 per cent of the cases. Thus, a single determination of the total protein by this method will give a value within ± 0.15 Gm. per 100 c.c. of the true value in 95 per cent of the analyses run. Similarly, it is unlikely that the value obtained for albumin is in error by more than ± 0.15 Gm.; for globulin plus fibrinogen, ± 0.07 Gm.; for fibrinogen, ± 0.017 Gm.; and for nonprotein nitrogen, ± 2.5 mg. per 100 c.c.

This concept of the accuracy of the method is based upon the assumption that an exact separation of the different protein fractions has been accomplished by the salting-out procedure. It is well known that a single "salting-out" will not quantitatively separate the two types of plasma protein, the albumin and globulin. In order to avoid this difficulty and still preserve the significance of analytical work, the terms "albumin" and "globulin" have come to mean those fractions of the plasma proteins which are separated by a single precipitation with sodium sulfate at a specific concentration and under controlled conditions. In the present work we have followed this accepted usage of the terms.

Chart 1.

Our choice of definitive conditions and concentrations of sodium sulfate is based largely upon the findings reported by Howe. This author¹⁰ has shown that the separation of fibrinogen with 10.6 per cent sodium sulfate gives values comparable to those obtained by other methods. In our work we have found that sodium sulfate in this concentration does not remove any of the protein from serum. It can, therefore, be concluded that no fraction other than fibrinogen will be separated from plasma unless it is adsorbed by the fibrinogen. In studying the protein precipitation with increasing concentrations of sodium sulfate,

Howe¹¹ found a critical zone between 20 and 22 per cent with plasma dilutions of 1:10. In our work the plasma dilution has been 1:20; however, this greater dilution has not produced a significant shift in the critical zone, as can be seen in representative curves given in Chart 1. In the curves of this chart an additional critical zone is shown at 18.5 to 19.5 per cent sodium sulfate, which was not found with some plasma samples. In all cases studied, covering a wide range of absolute values, the curves in the region of 21.5 per cent sodium sulfate were similar to those shown. Since this strength of sodium sulfate is usually employed for globulin precipitation, and does fall within the critical zone, we have continued to use a 21.5 per cent solution of the salt. Judging from the curves of Chart 1, it would seem that the use of 21.0 per cent sodium sulfate may be preferred, since this concentration falls more nearly at the center of the critical zone. It is probable that analytical results would not be significantly altered by this change. Although the separation of globulin and albumin is not complete, the values obtained on a given sample of plasma can be reproduced with considerable accuracy, and those on different samples of plasma should be comparable.

Chorine¹² has shown that the apparent plasma protein concentration may be markedly influenced by the nature and the amount of the anticoagulant used. According to this author's work, as well as that of others, heparin produces at most only a very slight change in plasma concentration. We believe, therefore, that our results give a true estimation of the amount of the circulating plasma proteins, unaltered by the anticoagulant which is added after the blood is drawn.

SUMMARY AND CONCLUSIONS

1. A method is presented for the separation and Kjeldahl analysis of the fibrinogen, albumin, and globulin of plasma.
2. A complete analysis of total nitrogen, nonprotein nitrogen, fibrinogen, albumin plus nonprotein nitrogen, and globulin plus fibrinogen may be done in duplicate on 0.8 c.c. of plasma.
3. A simple but accurate modification of existing micro-Kjeldahl procedures has been devised.

AN IMPROVED RAT CAGE FOR METABOLISM STUDIES*

HANS SELYE, M.D., PH.D., LUCY BASSETT, R.N., AND KAI NIELSEN
MONTREAL, CANADA

DURING the last few years the well-known wire drum and glass funnel metabolism cages have been in use in this department, but just as in other laboratories, we found that this cage had many disadvantages (contamination of feces and urine with food, washing of feces by urine, evaporation of urine, etc.). In the course of time many improvements have been made by members of this laboratory, using similar cages for metabolic studies, and gradually an entirely new type of cage was developed which eliminates most of the disadvantages mentioned. Since this metabolism cage proved very satisfactory, we wish to describe it here briefly in the hope that it will prove useful to other investigators as well.

Fig. 1 shows the complete unit of six cages with all parts assembled, as it appears when in use.

Fig. 2 shows the individual parts:

Cage. 7 by 8 by 5 inches of galvanized iron with wired top edge, having a hinged wire mesh door or lid (4 to 1 inches) fastened by means of a bronze door clip. The base of the cage is of wide wire mesh as indicated, to allow feces to drop through. Two outlets $1\frac{3}{8}$ inches in the front end of the cage enable the rat to obtain food and water. These holes must be placed high enough in the wall of the cage so that it becomes necessary for the rat to place its front paws on the edge of the hole when it takes food. This arrangement prevents the animal from lifting food into the cage where it would become mixed with excrements. Therefore, the height of the holes must be chosen according to the size of the rat. Above, center, is a small hole into which fits a rivet on the diet box which holds the box securely fastened to the cage front. An angle rest (as shown), front and back, supports the cage on the rack.

Diet Box. This box $5\frac{1}{2}$ by $2\frac{1}{8}$ by 4 inches of galvanized iron is divided into two compartments. One forms a food bin of wire mesh for gross food; the other, with a dividing shelf with hole in center, allows tip of water bottle to pass through; this shelf acts as a support for the bottle and prevents the eating of

*From the Department of Anatomy, McGill University, Montreal.
Received for publication, April 28, 1941.

the rubber stopper by the rat. Below these two compartments is sufficient space to insert a two-compartment drawer which is used to hold ground food on one side and to catch drips from the water bottle on the other. If extreme accuracy in determining of food intake is required, only ground food should be admin-

Fig. 1.

Fig. 2.

istered, since this can be measured exactly before and after the experiment by weighing the contents of the drawers. When the animal is being fasted, a small tray replaces the food drawer, fills in the space, and prevents the rat from crawling through the outlets into the diet box and the consequent loss of urine.

Rack. Legs are of $\frac{3}{4}$ by $\frac{3}{16}$ inch flat bar welded to 1 by $\frac{1}{2}$ inch angle iron; runway for funnels of 1 by $\frac{1}{2}$ by $\frac{1}{8}$ inch angle iron extending from end to end of the rack. Flat bar spacers $\frac{3}{4}$ by $\frac{1}{8}$ inch are welded to side bars front and back, spaced along the length of the rack at a distance of the width of each cage to prevent cages from sliding out of position over the funnels.

Funnels. Constructed of monel metal throughout are pyramidal in shape. Inserted in each funnel is a monel wire mesh rack similar in shape but somewhat less deep than the funnel and having a monel "toad stool" in the center. The toad stool is so constructed that the feces dropping from above roll off and collect in the rack at the base. The urine runs off the stool and drips directly through the mesh into the deeper funnel below without washing the feces. The funnel drains into an Erlenmeyer flask fastened by means of an airtight rubber stopper placed over the end of the funnel drip tube. This arrangement keeps evaporation of urine at a minimum.

As will be seen a supporting rivet is placed on both sides of the diet box; the use of one has already been described. The second is used when both fasting and thirst are desired. In this case it is possible to turn the diet box around, thus presenting a solid front toward the rat and covering the outlets of the cage.

The main advantages of this cage are:

- (1) No contamination of feces and urine by food.
- (2) No washing of feces by urine.
- (3) Achievement of extreme accuracy in measurement of both food and water intake.
- (4) Minimum urine evaporation.
- (5) The cages are relatively inexpensive because they are unbreakable and rust proof.

MEDICAL ILLUSTRATION

THE PHOTOGRAPHIC ASPECT OF LIGHT REFLECTION FROM HUMAN SKIN*

R. V. DENT, F.R.P.S., F.I.B.P., F.R.M.S., SHANGHAI, CHINA

CONSIDERABLE study has been given to the transmission and penetration of light *through* human skin, but it would appear from the literature that little attention has been given to the photographically important question of *reflection* of light from human skin. Experience reveals wide variations in the photographic appearance of skin taken under different conditions. (1) Such variations are attributed to the color sensitivity of the emulsion used, the color temperature of the light source, and/or the use of color filters. These explanations are inadequate since they place the subject on a par with the photography of colored objects and their translation into monochrome; they do not account satisfactorily for the need to use make-up to secure good photographs in color of the human face, and still less do they explain the cause of the variations in texture and definition shown by photographs of human skin taken by reflected light of different color temperatures. (2) More particularly, they afford no understanding of why skin photographs are waxlike under red light and show crisp definition under blue light.

The thesis of this paper is that human skin is a living tissue with definite characteristics with regard to the response of different wave lengths to light, and that the true explanation of the differences shown in photographs is to be found by ascertaining the *level* from which reflection of light is taking place. The basic point of this thesis is that different wave lengths of light are reflected from different levels (depths) of human skin, and this introduces four additional factors: penetration, absorption, reflection, and scatter, consideration of which is necessary for a complete explanation of the results obtained.

Skin varies considerably in thickness in different parts of the body, e.g., cross sections from the back show greater thickness of the stratum mucosum than similar cross sections from the back of the hand (Fig. 1, layer C). Similarly, skins from the palm of the hand or sole of the foot vary in thickness, and there is thus no one area standard for the whole body. For the purpose of experiment, skin from the back of the human hand was used throughout.

Fig. 1 is a photomicrograph of a transverse section of skin from the back of a hand of a Chinese and shows its structure and various layers. On it are shown the approximate levels at which it would appear by experimental photo-

*From the Department of Scientific Photography, Henry Lester Institute of Medical Research.

Received for publication, June 20, 1941.

Fig. 1.—Photomicrograph of a transverse section of skin from the back of the hand of a Chinese, showing its structure and various layers. On it are seen the approximate levels at which it would appear by experimental photographs that the light used was reflected.

graphs that the light used was reflected. Such levels must necessarily be approximate only, because, as previously stated, human skin in any event varies in thickness.

Experiments in photographing through skin and flesh indicate² that a powerful beam of light has considerable penetrating power and that, as is logical, the stronger and more concentrated the light, the greater the penetration and transmission. Such experiments further reveal that the transmission is mostly toward the red end of the spectrum and progressively decreases as it approaches violet and ultraviolet.³⁻⁸ This confirms results obtained photographically by reflected light.

17	Case of pellagra, Chinese	Panchromatic	Daylight	None
18	Case of pellagra, Chinese	Infra-red	Daylight	Infra-red

To demonstrate the correctness of our thesis a series of photographic experiments was carried out, using the following Ilford plates and filters, with a quartz mercury vapor lamp, half-watt lamps, and daylight. The plates used were:

Ilford "special rapid," an ordinary or nonecolor-sensitive plate of medium speed, sensitive from about 3,600 to 4,950 A.U., which is near ultraviolet to greenish blue. With this plate an Ilford tri-color blue filter cutting at 5,150 A.U. was used; thus, near ultraviolet and all the blue were used for taking the photograph.

Ilford "special rapid panchromatic," an orthopanchromatic type with the same development constant as the "special rapid," but sensitive from about 3,600 to 7,200 A.U. With this a beta filter was used once as a correction filter, because with half-watt light this gives practically full correction. This filter is a pale greenish yellow with a factor to H.W. of $\times 1\frac{1}{2}$ only.

Ilford "infra-red," an infra-red sensitive plate which, when used with its appropriate filter, records the action of rays between 7,000 and 9,000 A.U., with maximum sensitivity at about 8,100 A.U. The filter permits scarcely any

visible light to pass, and it is necessary to focus by a deep red filter and compensate by a slight increase in bellows extension when using it. The exact amount is $1/200$ of the focal distance of the lens.

All plates were backed and thus proof against halation. A Goerz Dagor F:6.8 - $8\frac{1}{4}$ inch lens was used, stopped down to F:22. Figs. 2 to 12 were taken with a vertical camera in a darkened room without any other light than that indicated; Figs. 16 to 18 were taken in a hospital ward by daylight, the patient being in bed and too ill to be moved. Development of the special rapid and special rapid panchromatic plates was routine, a developer of the D.76 type being used, with time and temperature for contrast of about 0.9 gamma. Exposures were based on meter readings, and prints were made on Kodak "Nikko" paper of medium contrast; this corresponds to grade 2; P.M.C. paper. No attempt was made to depart from the usual procedure and no contrasts were forced up or down by interference with normal development or printing.

Table I lists the experiments, and the illustrations show the photographic differences in skin-rendering.

RESULTS

Figs. 2 to 18 show definite changes in the photographic rendering of skin texture. The longer the wave lengths employed, the greater the loss of fine detail in the skin. The results are set forth here as a record because it is impossible for a half-tone reproduction to show the gradual changes as clearly as can be seen in the originals.

FIG.

APPEARANCE

- 2 Minutest lines and details of skin texture are clearly recorded; more is recorded than can be seen in daylight by the eye aided by a low-power magnifying glass.
- 3 This shows excellent rendering of texture which is slightly inferior to Fig. 1.
- 4 The general appearance is excellent, but the texture is not as crisp as in Fig 1.
- 5 The skin is commencing to show less texture.
- 6 The typical waxy appearance of the skin is caused by excess red light; the texture is poor.
- 7 Texture has completely disappeared; subcutaneous veins are visible.
- 14 This excellent skin texture shows the finest details.
- 15 There is complete absence of surface texture of the skin; underlying veins show through.
- 8 No texture can be seen but the veins are clearly visible.
- 9 Shows waxy appearance, with little texture and detail.
- 10 The general appearance is excellent, but crispness of lines is lacking.
- 11 Crispness of lines has reappeared, especially in the skin of the Chinese.
- 12 Minutest lines and details of skin texture are shown. Note the higher absorption of short waves by the hand of the Asiatic compared with that of the European.

The end differences shown are great. To make direct comparison between photographs taken by blue and by red light more simple, as occurs in tri-color separation negatives of human skin, the portion of skin around the knuckles

of the middle and third fingers in Figs. 3 and 6 have been enlarged and are shown in Figs. 19 and 20. These are not the extremes, which would be Figs. 2 and 7, 14 and 15, and 9 and 12. Figs. 3 and 19 show the approximate effect secured in normal sunlight by using an ortho film, whereas Figs. 6 and 20 are those secured on a hypersensitive or type 3 panchromatic film by nitro-phot lights, or lights abundant in red rays.

These two comparisons are, therefore, the most important from a practical photographic aspect, since the conditions are commonly met with in ordinary practice.

DISCUSSION

The photographs reveal that as the wave length of light used for illumination is increased, the surface texture that can be photographed is progressively diminished and finally entirely lost. This can only mean that reflection of the rays that are actually making the photographic negative is taking place from different levels of the skin. Therefore, the photographic rendering of human skin is not solely a matter of color correction and color sensitivity, but is closely connected with the inherent response of skin as a living tissue to light thrown upon it.

Figs. 16, 17, and 18 are comparison photographs of the skin condition on the hands of a patient with pellagra. The panchromatic version (Fig. 17) is a good representation of the visual appearance. The blue plus near ultraviolet version (Fig. 16) accentuates surface lesions and reveals more than the eye sees; the infra-red version (Fig. 18) shows that the true extent of serious damage is limited to the fingers. It is obvious that such photographs are of great diagnostic value.

Table II sets forth an interpretation of the results of the experiments.

TABLE II

LIGHT	ABSORPTION	REFLECTION LEVEL	REFLECTION INTENSITY	SCATTER
Near ultraviolet to blue	4	A to B	1	1
Blue green to orange	3	B to C	2	2
Red	2	D	3	3
Near infra-red	1	E and F	4	4

The numbers 1 to 4 are arbitrary indicators for the amount absorbed, reflected, and scattered, as follows: (1) minute; (2) little; (3) moderate; (4) considerable. For practical purposes it is sufficient to divide the light into these four divisions, and in any case the varying thickness of skin makes exact measurements valueless.

Fig. 17.—A case of pellagra in a Chinese taken on a panchromatic plate with daylight illumination.

Fig. 18.—A case of pellagra in a Chinese taken on an infra-red plate with daylight illumination.

Fig. 19.—This illustration is an enlargement of the center section of Fig. 3. It was taken on a special rapid plate through a tri-blue filter with the half-watt light as illumination.

Fig. 20.—An enlargement of the center section of Fig. 6. This was taken on a panchromatic plate through a tri-red filter with the half-watt light as illumination.

It was mentioned earlier that the stronger and more concentrated a beam of light, the greater its transmission through skin and flesh. This introduces yet another factor, the strength or volume of light employed on a given area. The latter has a distinct effect on photographic rendering. This would appear to furnish one of the reasons why overlighting is disastrous to good photographs of skin texture, since evidently it results in abnormal penetration of light into the skin, with a consequent accentuated reflection from the lower layers causing excessive scatter.

Further, these experiments show clearly that the modern hypersensitive panchromatic film (type C) used in conjunction with half-watt light is not the ideal combination for work on skin. A study of the old photographs published in textbooks reveals that in general they are superior as records of skin to some more recent examples. In this sense there has been retrogression in the technical photography of skin texture.

In photographing human skin for medical records it is of paramount importance that the visual appearance of the texture and skin lesions present be clearly recorded. This is particularly necessary when a specific pathologic condition is to be illustrated, for unless the diseased condition is plainly shown the photograph is worthless.

Both normal and diseased skins have texture, but the recording of this texture is not achieved photographically unless basic requirements to secure it are known and fulfilled. Medical photography is decidedly different from portraiture; the latter aims at the suppression of defects which it is the precise function of the biologic photograph to record. The approach to the two types of subject is, therefore, entirely different.

The surface of human skin is covered with a multiplicity of fine criss-crossed lines, thus giving it the marked texture characteristic and typical of its appearance. Skin is a good reflector of normal daylight; it reflects more of the longer waves and absorbs more of the shorter, and strongly polarizes light reflected between the angles of 32 and 37 degrees. The elimination of reflections by polarizing screens destroys its living appearance and affects the recording of texture; this is evidence that it is solely the reflected light which governs the photographic appearance of skin.

The two basic factors are thus inequalities of surface and variations in reflection. Illumination must take both into consideration and so light the subject that the minute hills and dales of the skin surface are not flattened by being flooded with light. The quality of light must be such that reflection is taking place from some known portion of the skin, that is, at some known position with regard to its surface. The first requirement is standard for all photography; illumination must be so arranged that the subject is shown properly. The second is generally ignored, but is of fully as great importance. It is generally assumed that the problems are much the same as with portraiture and that, provided the lighting is directionally correct and a suitable emulsion is used, results will be as good as can be secured. This is not so.

Light thrown on human skin penetrates it, and is absorbed and reflected by it, the degree of penetration, absorption, and reflection depending upon its component wave lengths. The photographic definition secured in a negative

is considerably affected by the amount of penetration taking place and the consequent depth of reflection from the inner surfaces of the skin. This has little connection with color-rendering into monochrome as such, for the problems are specific to human skin.

Penetration plus reflection obviously causes scatter, depending upon the depth of the intervening layers of skin which have been traversed by light. The deeper this penetration, the more scattering will be the reflected rays, since such rays are scattered not only on entering but also on being reflected back to the surface; hence the difference in appearance of the same skin photographed by light of different spectral quality.⁹ It is clear that an understanding of the cause of this difference enables the securing of exactly the type of photograph required.

It can be accepted as a fact that penetration through skin of the light of the complete visible spectrum, which for the purposes of this paper is taken to include the near ultraviolet and near infra-red rays, is greater as the wave length of the light increases.⁸ Much work has been done along these lines, with interesting results confirmed by practical photographic experience.⁴ Normally, photography is entirely dependent upon reflected light; therefore, the reflection levels rather than absorption and transmission are photographically of greater importance.

Light has a threefold action on impact with skin: absorption, penetration, and reflection. Photographically, light absorbed by a subject is lost and of no value. Since the longer wave lengths penetrate more deeply, those that are not absorbed must necessarily be reflected back to the surface from the maximum depth of penetration, and this is the light used to make the photograph and govern the sharpness of the image secured. That is, other things being equal, the photographic rendering of skin is fixed definitely by the quality of light used in the making of the photograph, and it is impossible to change this fundamental record by any subsequent chemical tinkering with the negative or print. It should now be clear that it is not a matter of color-rendering as such, because texture and definition have no direct connection with the interpretation of color into monochrome.

Although absorption is outside our subject, it is photographically important because it not only affects exposure time but also governs the color-rendering. When there is much absorption, the subject photographs dark, and vice versa. A good example of this is green vegetation photographed by blue light (or on a noncolor-sensitive emulsion) as compared to the same subject photographed by infra-red. Green leaves absorb ultraviolet and deep blue but reject deep red and infra-red; therefore, the first photograph will show the subject dark and the second will show it light in tone.^{10, 11} An even more striking example is a comparison between the brown fur of a dog and the brown feathers of birds; visually there is little difference in color, but photographically there is a wide difference in exposure time required owing to the absorption of ultraviolet by brown fur and the strong reflection of ultraviolet by feathers. Measurements with photoelectric meters reveal this difference and the camera confirms it. Nature has given the animals protection against receiving insufficient or too large doses of ultraviolet. The bird is exposed to too much while flying in the

sky, whereas the animal needs all the chemical rays it can get to maintain its supply of vitamin D. There is unquestionably a similar protective system at work in the skin of man, which accounts for the selective absorption of light and its variation in the different races of mankind according to the climatic conditions under which he lives.

There are three methods of controlling the quality of light used in the making of a photograph:

1. The interposition of a light filter at some point between the light source and the sensitive film.
2. The use of light sources rich or deficient in certain wave lengths.
3. Selection of the rays by the choice of film.

The final negative quality and photographic rendering of skin will be strongly affected by these fundamental factors. It is notorious that the use of modern extreme, red-sensitive emulsions with artificial light abnormally rich in the longer wave lengths gives a waxy, textureless appearance to the skin, and our contention is that the reason for this is reflection from beneath the skin surface.

It is an interesting speculation that there may be an interference effect at the skin surface which may produce *stationary waves* somewhat along the lines of the Lippmann process of color photography.¹²

SUMMARY

The photographic appearance of human skin is modified by the reflection depths of the component wave lengths of the light used for illustration, and as such it is not a matter of color correction, as ordinarily understood, but the level of penetration and consequent reflection and scatter of the light used. Evidence is offered in the form of a series of photographs taken by various illuminants.

I wish to thank Professor Bernard E. Read, acting director of the Henry Lester Institute of Medical Research, for his help in the writing of this paper, and Dr. L. S. Kau, Tissue Pathologist of the Institute, for supplying the sections of skins required.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

SULFAPYRIDINE, Level of in Blood of Children Following Dosage by Weight, Cullen, G. E., and Wilson, A. T. *Am. J. Dis. Child.* 60: 891, 1940.

A simple and convenient standard system of dosage of sulfapyridine on the basis of body weight is recommended: 1 grain per pound of body weight per twenty-four hours, with an initial dose of half the calculated twenty-four-hour dose and with the total daily dose not to exceed 80 grains.

Groups of infants and children of different ages have, on the average, approximately the same levels of free sulfapyridine in the blood when they are given the same dosage according to body weight.

Individual patients receiving sulfapyridine in a dosage based on body weight show only moderate fluctuations in the levels of the drug in their blood from day to day or throughout a single day.

The averages of several individual values of patients receiving sulfapyridine in a dosage by body weight vary widely from patient to patient.

In view of the several types of rather marked and unpredictable variations, it must be concluded that it is desirable to make frequent determinations of the actual level present in any given patient and subsequently to adjust the dosage according to the level desired.

URINARY TRACT, Chemotherapy in Nonspecific Infections of, Alyea, E. P., and Roberts, L. C. *J. A. M. A.* 115: 1345, 1940.

The sulfonamide drugs are excreted by the kidneys in a manner exactly similar to phenolsulfonphthalein.

In vitro and in vivo studies show the specificity that the sulfonamide drugs have for different bacteria and different strains of the same bacterium.

Experimental studies in vitro are not necessarily entirely comparable in vivo.

The action of sulfonamide drugs in infections of the urinary tract depends more on the tissue reaction than on direct bactericidal action in the urine.

Mandelic acid is an excellent drug for infections with colon bacilli and *Streptococcus faecalis*.

A comparison of the colon bacillus infections treated with sulfanilamide and sulfapyridine shows practically the same, or 81 per cent, cured.

A comparison of the same drugs in staphylococcal infections shows that with sulfapyridine 75 per cent were cured and with sulfanilamide 62.5 per cent.

Response to the sulfonamide drugs is rapid, usually within two or three days.

Infections complicated by other pathologic changes do not respond as favorably as the simple infections.

A comparison of sulfanilamide and mandelic acid therapy in various types of cases shows that sulfanilamide is usually preferable.

Evidence shows that the high drug concentration in the urine usually thought desirable is not necessary for cures.

A dosage of 1.7 Gm. of sulfanilamide a day with forced fluids produced as good results as 3 Gm. a day with restricted fluids. The same is true with sulfapyridine.

Many patients cannot take the large doses with restricted fluids, but the recommended small dosage is easily tolerated by all.

RENAL FUNCTION: Relative Significance of Concentration of Inorganic Sulfate in the Serum and of Its Renal Clearance, Goudsmit, A., Jr., and Keith, N. M. Arch. Int. Med. 66: 816, 1940.

Comparative studies of blood urea, urea clearance, serum sulfate, and sulfate clearance were performed on 50 patients. The majority were suffering from diffuso arteriolar disease with hypertension of various degrees of severity; most of the remainder, from chronic glomerulonephritis and other diseases of the urinary tract. The selection of the patients was conducted in such a manner that half of the group would have normal and the other half increased concentrations of sulfate in the serum.

The increased concentration of serum sulfate was found to occur in diffuse arteriolar disease with hypertension groups 3 and 4 in 4 of every 5 cases, the urea clearance, the value for blood urea, and the sulfate clearance indicating renal damage with decreasing frequency. The correlation of renal damage sufficient to bring about actual retention of an end product of normal protein metabolism and hypersensitive vascular disease severe enough to be associated with retinitis is significant. It is assumed that arteriolar disease may well be responsible for both the retinal and the renal changes.

Generally speaking, in the more severe degrees of hypertension, as contrasted with the milder forms, there is a far greater probability of retention of either urea or sulfate in the blood than of decreases in the renal clearance of these substances. In this respect the patterns of excretion of urea and of sulfate are essentially similar. However, whereas the association of retention of urea in the blood and a normal value for urea clearance was observed in only one instance, 12 instances of increased serum sulfate in the presence of a normal value for sulfate clearance were observed.

The increase of the concentration of serum sulfate itself is held responsible for this behavior, and an analogy is seen with observations on experimental animals as well as on human volunteers, in whom the intravenous injection of sodium sulfate leads to considerable increases in the value for sulfate clearance without significantly changing renal function otherwise. In accordance with the analogy drawn from these experimental observations, the ratio of sulfate clearance to urea clearance is significantly increased in the cases of those patients who have increased values for (endogenous) sulfate in the serum as compared to those with normal values for serum sulfate.

Thus, although conclusions of prognostic significance in renal disease should not be based on the value for serum sulfate any more than on any other single laboratory index, determination of this index is a valuable adjunct in appraising renal function, and the pattern of excretion of sulfate is of considerable interest to the student of renal and vascular disease.

BLOOD SUGAR, Normal Values in Children, Rudesill, C. L., and Henderson, R. A. Am. J. Dis. Child. 61: 108, 1941.

A total of 288 blood sugar determinations were made by the Folin-Wu method on 144 nondiabetic children from 2 to 15 years of age, inclusive. Values for both fasting and 11 A.M. blood sugar were determined on the same day and the reports were correlated.

There is no practical difference between fasting and 11 A.M. blood sugar values, since both fall within normal limits.

If the Folin-Wu method is used, normal fasting blood sugar values in nondiabetic children from 2 to 15 years of age range from 70 to 105 mg. per hundred cubic centimeters.

A review of the literature indicates that the range of normal blood sugar values in infants is probably from 60 to 100 mg. per hundred cubic centimeters in most cases.

STAPHYLOCOCCI, Technic of, The Coagulase Test for, Fisk, A. Brit. J. Exper. Path. 21: 311, 1940.

Within wide limits the amount of sodium citrate does not materially affect the coagulase test.

Citrated plasma diluted 10 to 20 times gives satisfactory results.

Human plasma from different individuals does not show wide variations in clotting time.

The citrated plasma remains suitable for the test for several weeks if kept undiluted under sterile conditions.

Staphylococci growing in a variety of media produce coagulase. Of a number of liquid media, broth gave a culture which produced coagulation most quickly. Agar cultures may also be employed, in which case it is best to emulsify the organism in broth to form an even suspension of an opacity approximately equal to that of a twenty-four-hour broth culture.

There is an optimum ratio between amount of organism and amount of plasma.

The reaction occurs most quickly at 37° C.

The method suggested for the performance of the coagulase test is as follows:

1. Dilute citrated human plasma tenfold with normal saline.
2. Place 0.5 ml. of this diluted plasma in two small test tubes.
3. To one of these add 5 drops from a capillary pipette (approximately 0.125 ml.) of an overnight broth culture of staphylococcus or a suspension of an agar culture made in broth to an opacity approximately equal to an overnight broth culture. The second tube serves as a control and must show no clotting. Incubate the tubes at 37° C.
4. Examine the tubes after half an hour and at intervals for six hours. (Clotting of the plasma usually occurs within one hour.)

STAPHYLOCOCCI, Use of Slide Agglutination to Determine Pathogenicity of Staphylococci, Christie, R. Australian J. Exper. Biol. & M. Sc. 18: 397, 1940.

A total of 335 strains of staphylococci of human origin and 57 strains of animal origin have been examined.

Of 269 coagulase-positive strains, 257 were agglutinated by a mixture of three antisera prepared from coagulase-positive strains; nine strains were auto-agglutinable and could not be tested. One human and two animal strains were not agglutinated; the human strain was serologically related to the coagulase-positive strains in spite of its inagglutinability with the serum mixture. Of 123 coagulase-negative strains, 120 were not agglutinated, two were auto-agglutinable, and one was agglutinated slightly.

An attempt to produce agglutinating sera with coagulase-negative strains which would agglutinate coagulase-negative and not coagulase-positive strains was unsuccessful.

HYPOPROTHROMBINEMIA, Intravenous Use of 2-Methyl-1, 4-Naphthoquinone in, Norcross, J. W., and McFarland, M. D. J. A. M. A. 115: 2156, 1940.

2-Methyl-1, 4-naphthoquinone has been administered intravenously to 22 patients. It has proved to be efficient in raising the prothrombin level. Bile salts were not necessary for this response.

With the exception of local distress for short duration at the time of injection, no toxic manifestations have been observed.

The minimal effective intravenous dose of 2-methyl-1, 4-naphthoquinone in the adult was found to be 2 mg.

In cases uncomplicated by liver impairment a 2 mg. dose given intravenously raised the prothrombin level from 50 per cent to 80 per cent in an average of seven and one-half hours and to 100 per cent in an average of twenty hours.

A 2 mg. intravenous dose kept the prothrombin level above 90 per cent of normal for four or more days unless liver damage was present.

Severe liver damage permitted only a slight response to intravenous 2-methyl-1, 4-naphthoquinone. If liver impairment was less marked, the effect was manifested in a slower onset of response, a lessened height of response, and a shorter duration of response.

Bleeding was rapidly and effectively controlled unless severe damage was present.

The intravenous route of administration has great value in patients for whom oral administration is difficult or impossible, as well as in those in whom rapid cessation of bleeding is imperative.

PNEUMONIA in Children, Treatment of, With a Single Dose of Sulfapyridine, Platt, L.
Am. J. Dis. Child. 60: 1019, 1940.

In the children included in this study the single-dose method gave satisfactory levels in the blood in most instances, and the clinical results were as good as, if not better than, those in the group that received multiple doses. If the results are as good, it would seem desirable to adopt a single-dose method, for the following reasons:

1. It is simpler, interferes less with the child's rest and sleep during the time when he is most ill and is less demanding on the nursing staff.

2. It decreases the incidence of the most common toxic effect, nausea and vomiting.

For the ordinary case of uncomplicated pneumonia it would appear that 0.3 Gm. of sulfapyridine per kilogram of body weight administered in one dose will give satisfactory results. Lower doses are not so consistent in giving levels in the blood above 4 mg. per hundred cubic centimeters. Although the lower levels gave satisfactory results, it would seem safer to use the larger dose. If it is thought desirable to maintain levels in the blood above 4 mg. per hundred cubic centimeters for more than twenty-four hours, the dose can be repeated at eighteen- to twenty-four-hour intervals. Such repetition is probably advisable when the patient cannot be watched closely. It will probably decrease the number of cases in which a secondary rise in temperature occurs.

After the oral administration of a single dose of 0.3 Gm. of sulfapyridine per kilogram of body weight, the free sulfapyridine in the blood usually reaches levels of at least 4 mg. per hundred cubic centimeters within a few hours. In most cases a considerable concentration persists for at least twenty-four hours.

In some cases the highest levels of the blood occur after twenty-four hours, indicating that absorption from the gastrointestinal tract may continue for that length of time.

The administration of a single dose of sulfapyridine of 0.3 Gm. per kilogram of body weight to children with pneumonia gives satisfactory therapeutic results.

Levels in the blood above 2 mg. per hundred cubic centimeters give satisfactory results in most cases of pneumonia in childhood.

The use of the single dose method simplifies the treatment of pneumonia and decreases the incidence of toxic effects.

Item

Announcement will shortly be made of unassembled examinations to be given for the following positions in the West Virginia State Health Department:

Director, Hygienic Laboratory	\$320-375
Senior Bacteriologist	150-200
Senior Serologist	150-200

Residence in West Virginia has been waived in consideration of the applications for these positions. However, residents of this state may be given preference in making appointments. Complete information may be obtained by writing directly to the Merit System Council, Morgantown, W. Va.

PROGRESS

ALLERGY OF THE ABDOMINAL ORGANS*

MATTHEW WALZER, M.D., BROOKLYN, N. Y.

ALTHOUGH it has long been recognized that abdominal organs may participate in allergic reactions, there have been relatively few reports dealing with this subject. Because of the inaccessibility of the abdominal organs, considerable speculation has arisen as to the seat of the allergic processes and the nature of these reactions.

My colleagues H. Straus, I. Gray, M. Harton, S. Livingston, and D. Grayzel, and I have attempted to reproduce and study allergic reactions of the abdominal organs under experimental conditions. Investigations, not feasible in human beings, were carried out in the rhesus monkey, in which it is possible to induce allergic reactions closely resembling those occurring in man. It is hoped that the brief analysis of these experimental findings presented herewith will facilitate a better understanding of allergic reactions occurring within the human abdomen.

The primary experimental principle applied in most of these investigations was the production of allergic reactions in tissues which had been passively sensitized locally with human serum, containing atopic reagin antibodies. These sera were obtained from allergic individuals who were clinically very sensitive to such allergens as cottonseed, peanut, fish, egg, etc., and who showed very strong cutaneous reactions when tested with weak extracts of these allergens. This cutaneous sensitivity could be transferred to the skin of normal individuals by an intracutaneous injection of 0.05 ml. of the reagin-containing serum. The allergic reaction at the sensitized site was elicited from twenty-four to forty-eight hours later by feeding the related antigen, i.e., peanut, cottonseed, fish, egg, etc., or by an intravenous injection of an extract of that antigen. Oral administration of the antigen was regularly followed, within from five to

*From the Allergy Division of the Jewish Hospital, Brooklyn

fifteen minutes, by the entrance of traces of the antigen into the circulation and by the formation of a wheal at the sensitized cutaneous site.¹ This reaction resulted from the union of the circulating antigen with the reagents, which had remained fixed in the skin at the site of sensitization. The intravenous injection of the antigen usually resulted in a more rapid onset and in a more intense reaction than that which occurred following enteral administration. Both methods of inducing the allergic reaction were employed, depending upon the needs of the experiment. In the earlier investigations sensitization was confined to the skin; in later studies, mucous membranes, other tissues, and even complete organs were successfully sensitized.

METHODS OF EXCITING ALLERGIC REACTIONS IN ABDOMINAL ORGANS

Under physiologic conditions offending allergens may reach and excite abdominal organs in two ways. Any specific excitant introduced into the alimentary tract may, by direct contact, induce allergic reactions in the organs through which it passes. It is also possible for any antigen which gains entrance into the blood stream to reach sensitive abdominal organs by this route. The most natural way for antigens to reach the circulation is by way of the alimentary tract. In our studies on normal individuals, fish, egg, nut, cottonseed, mustard, milk, and other antigens almost routinely appeared in the blood stream within from two to thirty minutes after their ingestion.¹ This rapid absorption of the allergen accounts for many of the explosive allergic reactions which have been seen to follow, almost immediately, the ingestion of offending allergens. These reactions may affect widely separated organs, including parts of the digestive system distant from the site of administration and absorption of the excitant. That any one of several closely related organs or only one type of tissue may participate in an allergic reaction, while others in the same individual appear to remain unaffected, is recognized as a common occurrence in allergy, although an adequate explanation for this phenomenon is still lacking.

Passage of allergens into the circulation has been demonstrated to occur almost regularly from all parts of the alimentary tract, including the esophagus, stomach,² duodenum,³ ileum, colon,⁴ and rectum.⁵ Gastric acidity is an important factor in influencing the amount and rapidity of allergenic absorption. Gastric hyperacidity definitely retards and diminishes absorption, not only from the stomach and duodenum but also from the rectum.⁵ Hypoacidity and anacidity produce the opposite effects. Absorption of allergens may also be delayed or prevented by the previous oral administration of other food, oil, kaolin, pepsin, hydrochloric acid, or similar substances.⁶ Alcohol promotes and accelerates absorption. The importance of these experimental findings in the management of food allergies is obvious.

Allergen, administered rectally, may enter the blood stream as rapidly as that introduced into the duodenum, and even more rapidly than that taken by mouth.⁵ It should also be remembered that other mucous membranes and lining surfaces permit the rapid passage of antigens. Hence, sensitive abdominal organs may be specifically excited by allergens which have been absorbed by way of the upper and lower respiratory tract^{7, 8} and through the vaginal and cervical

mucous membranes.⁹ The same may be said in relation to allergens which have been introduced into the pleural, pericardial, and peritoneal cavities,¹⁰ and into the urinary bladder¹⁰ and the gall bladder.⁴ Similar effects may also occur when antigen is rubbed into the skin¹¹ or administered by the intraspinal,¹⁰ intramuscular, intracutaneous, or subcutaneous routes.

Minute quantities of antigen, containing as little as 0.0001 mg. of nitrogen, when given intravenously, have proved sufficient to induce maximal allergic reactions in passively sensitized tissue.⁵ The severity of allergic symptoms may, therefore, be far more intense than might be expected from relatively slight contact with the excitant. Moreover, it seems likely that in allergic incidents involving abdominal as well as other shock organs, observers are apt to overlook the importance of less obvious contacts with excitants, such as those occurring by inhalation and by vaginal, rectal, or parenteral administration.

ALLERGIC REACTION IN PASSIVELY SENSITIZED INTESTINAL MUCOUS MEMBRANE IN HUMAN BEINGS

An insight into the nature of the allergic reaction in the human alimentary mucous membranes was obtained by studies of the experimental allergic reaction induced in the sensitized mucous membrane of the rectum.¹² In this study the antigen was administered either rectally or orally. The reaction at the sensitized mucous membrane site appeared in from five to twenty minutes.

Edema, hyperemia, and hypersecretion were the cardinal characteristics of the reaction developing at the sensitized mucous membrane site. Edema appeared first, associated with a pallor of the mucous membrane which was superseded, within a few minutes, by marked hyperemia. Hypersecretion of mucus occurred over the affected area. The entire reaction reached its peak within fifteen minutes and then began to recede rapidly, disappearing almost completely in about an hour. The subjective symptoms varied with the site of sensitization. Pruritus, rectal fullness, and burning, as well as a desire to empty the bowel, were experienced in variable degree, depending on the site of the reaction. The closer the reaction to the anus, the more varied and intense were the symptoms. Few subjective symptoms were noted when the distance from the anal orifice was as much as 6 cm.

To observe the reactions in the ileum and colon mucous membranes, two patients, one with an ileostomy, the other with an ileocolostomy, were studied.⁴ Sites on the exposed mucous membranes were sensitized by intramucosal injections of reagin-bearing serum. Within four or five minutes following oral administration of the antigen, the allergic reaction started. Pallor and hypersecretion of the sensitized area were followed, in a few minutes, by edema which became progressively greater for about half an hour (Fig. 1). The pallor was replaced by marked hyperemia and the secretion of mucus became profuse. The entire reaction receded at the end of an hour. Except for itching or burning of the surrounding skin, no subjective symptoms accompanied these reactions.

Direct application of antigen, on an applicator, to a sensitized mucous membrane site on the rectum¹² or colon,⁴ produced an allergic reaction of moderate intensity in about four or five minutes. As a result of this application, sufficient antigen was absorbed to excite a previously sensitized cutaneous site. At

this time, the mucous membrane sites began to react maximally. This sequence of events, noted repeatedly in these and other experiments, again emphasizes the importance of blood-borne antigen in the elicitation of maximal allergic responses. Although direct contact of mucous membranes with offending allergens may produce severe reactions, it seems likely that, in most instances, reactions of maximal intensity are caused by blood-borne excitants. It is of interest to note that, in the above experiments, the antigen, which was gently applied on an applicator to the sensitized mucous membrane site (without rubbing), reached the circulation by passing through the sensitized area itself. Sensitive mucous membrane, therefore, is not a barrier to the absorption of offending allergens.

Fig. 1.—Above, Human ileum (left) and colon (right) at onset of allergic reaction. Below, Human ileum (left) and colon (right) after thirty minutes, at height of allergic reaction. Arrows mark sites of sensitization.

ALLERGIC REACTIONS IN PASSIVELY SENSITIZED ORGANS IN THE MONKEY

In the monkey sensitization of mucous membrane was accomplished with laparotomy under sterile precautions, by the injection of sensitizing serum into mucous membranes exposed by incisions into various organs.¹³ One or more sites were sensitized in areas as far away as possible from the neighborhood of the incision into the organ. At times intussusception of one organ into another which had been opened permitted sensitization of the first without actual incision into it. Either the oral or the intravenous method of excitation of the allergic reaction was employed.

In studies on the passively sensitized stomach¹³ in the monkey, the most pronounced changes occurred in the uncut organ in which the mucous membrane had been sensitized at several sites, through an opening in the duodenum, near the pylorus. The administration, by stomach tube, of the meal containing the

antigen resulted in the onset of the allergic reaction within three or four minutes. At first the walls of the organ became pale and turgid. Peristaltic waves increased in frequency and intensity. Prepyloric and pyloric spasm developed and persisted for long periods of time. The size of the organ became definitely diminished. On section the mucous membrane was seen to be markedly hyperemic and edematous. This was particularly noticeable at the pylorus, which was almost closed by thickening of the mucous membrane on the gastric side, while the lining of the unsensitized duodenum remained normal. Mucus flowed excessively from the gastric mucous membrane.

Fig. 2.—Opened gall bladder in the monkey showing allergic reaction involving the lower one-half of the organ

In the cecum and colon, in which single sites of the mucous membranes had been sensitized, similar reactions developed.¹³ With the onset of the allergic reaction, blanching of the affected gut developed, followed in a short time by local swelling and edema. Hyperperistalsis became noticeable in this region of the bowel and, in some instances, definite tonic contractions, lasting for five or ten minutes at a time, were noted at the sensitized area. On section of the bowel, the mucous membrane revealed the usual picture of hyperemia, marked edema, and hypersecretion.

Microscopic examination¹⁴ of tissue taken from the site of the allergic reaction showed the lining cells of the mucosa to be only slightly involved. The submucosa in particular, and, to some extent, the serosa were edematous. Their vessels were distended and showed margination of the white blood cells. Around the vessels and throughout the tissues were infiltrations of eosinophiles, lymphocytes, large mononuclear and some polymorphonuclear leucocytes.

In experiments on the gall bladder¹⁵ incision into the organ was avoided. Sensitization was effected by injecting the sensitizing serum directly into the wall of the organ at several sites. The allergic reaction was induced by intravenous injection of the antigen. Within a minute or two that part of the organ which had been sensitized grew pale and the surface vessels became more prominent. This part of the wall became edematous and appeared to bulge and throb. Spasm was not observed in any part of the organ in any of these experiments.

On section of the gall bladder at the height of the reaction the wall of the involved area appeared several times thicker than that of the unaffected part. As in the other organs, edema, hyperemia, hypersecretion, and loss of surface markings characterized the allergic mucous membrane (Fig. 2).

Fig. 3A.—Microscopic picture of normal part of the gall bladder in the monkey.

Microscopic examination of the allergic gall bladder wall revealed the mucosal epithelium to be intact and only slightly affected (Fig. 3). The lamina propria was markedly edematous. The blood vessels were engorged and showed some margination of white blood cells. There was a pronounced cellular infiltration consisting of eosinophiles, lymphocytes, large mononuclear cells, and some polymorphonuclear leucocytes. The edema invaded the other layers of the gall bladder, spreading between the muscle bundles and fibers. Vascular congestion and cellular infiltration also were present in these areas but not to the same degree as in the lamina propria. The nonsensitized part of the organ showed none of these changes on microscopic examination.

ALLERGIC REACTIONS IN THE ALIMENTARY TRACT OF FOOD-SENSITIVE CHILDREN

Special roentgenographic studies in food-sensitive children, made by Fries and Zismor,¹⁶ rendered it possible to visualize, to some extent, the behavior of the human alimentary tract during allergic reactions. Thirty children, who were known to manifest gastrointestinal disturbances following the ingestion of certain foods, were first studied by fluoroscopic and roentgenographic observa-

tions following the ingestion of a standard barium meal. About a week later a similar meal, to which, without the patient's knowledge, a small amount of an offending allergen had been added, was administered under the same experimental conditions. The x-ray findings were then compared with those of the control series.

Some characteristic changes were found in many of these children, following the ingestion of the allergen-barium meal. In most instances a pronounced gastric retention developed. The stomach appeared hypomotile and hypotonic. The duodenal bulb, in many cases, seemed to fill with difficulty. At times barium was still observed in the stomach six hours after the allergen-barium meal, whereas the control series had shown complete emptying of the stomach in a much shorter time.

Fig. 3B.—Microscopic picture of gall bladder wall involved in allergic reaction.

The progress of the allergen-barium meal through the small bowel varied with the patient. In some its passage was definitely accelerated, while in others no unusual feature was detectable in its progress. In the large bowel evidences of spasm or dilatation were frequently observed. This finding was not constant and, whenever present, it did not affect all portions of the bowel equally.

The administration of allergen-barium enemas to the allergic children usually precipitated spasm in some parts of the large bowel. The seat of the tonic contractions varied with the patient, although the transverse colon seemed to be affected most frequently. In some dilatation of the bowel resulted from this contact with the offending allergen.

The oral administration of the allergen-barium meal in 30 food-sensitive children produced subjective symptoms in 73 per cent.¹⁷ Nausea was noted most frequently, occurring in 43 per cent. Vomiting, usually within several minutes after administration of the meal, occurred in 23 per cent. In 20 per cent abdominal pain was pronounced. This pain had no characteristic localization, but

was most frequently reported to be in the center of the abdomen. Burning or itching of the mouth or throat was a complaint of only 7 per cent.

Abdominal pain was a more frequent and severe symptom among the 16 children who received allergen-barium enemas. Seventy-five per cent of these experienced severe abdominal pain. Nausea occurred in only 6 per cent of this series, but tenesmus was a complaint of 24 per cent.

ALLERGIC SHOCK TISSUE

The foregoing findings suggest apparent similarities in the allergic reactions of the gastrointestinal tracts in man and in the passively sensitized rhesus monkey. In both, edema, hyperemia, and hypersecretion characterize the allergic mucous membranes. In both, the emptying time of the stomach is delayed, following the ingestion of the offending allergen. Spasm of the small and large bowels may occur in both, although it is not so pronounced or so regular a finding in man as it is in the monkey. Dilatation of the bowel was observed more frequently in man.

These observations render it necessary to reopen the question as to whether the smooth muscle is the seat of the allergic reaction in man and plays the same role as shock tissue that it does in the anaphylactic reaction of the guinea pig, rabbit, and dog. This assumption, accepted as fact in some quarters, finds no support in the above findings. Smooth muscle spasm, which characterizes the anaphylactic reaction in the guinea pig, is, by no means, a constant manifestation of the allergic reaction of the human bowel. Moreover, on testing intestinal smooth muscle of the passively sensitized monkey by the Schultz-Dale technique, Albert and I¹⁸ found no evidence of sensitivity of this tissue. Negative results were obtained with these intestinal strips, despite the fact that these animals had been passively sensitized with large doses of human reagin-bearing sera of high titer, which easily produced sensitization of the skin and mucous membrane of the same animals. Even when anaphylactic (precipitin) antibodies were employed for passive sensitization of the rhesus monkey, no evidence of sensitivity could be found in the smooth muscle of intestinal strips.¹⁹ Negative results were also obtained in monkeys in which active sensitization was attempted using the technique suggested by Kopeloff, Davidoff, and Kopeloff.²⁰

In man, the only smooth muscle studies reported are those of Tuft,²¹ who tested uterine muscle strips obtained during the cesarean section of a woman with precipitins and reagins to horse serum in her blood. Tests with horse serum, by the Schultz-Dale technique, failed to produce any specific contractions in the uterine muscle. It, therefore, seems unlikely that, in man as well as in the monkey, smooth muscle is the shock tissue. This viewpoint finds further support in the histologic studies of the allergic reactions already described. It will be recalled that, although edema, vascular dilatation, and cellular infiltration involved the connective tissue around the muscle bundles and between the muscle fibers, the latter did not seem to share in the inflammatory process.

It also seems unlikely that the epithelial cells of the mucous membranes are the seat of the allergic reactions. These cells did not appear to be seriously altered in the histologic studies of the allergic tissues. Moreover, the

topical application of an allergen to the surface of the sensitized rectal or intestinal mucous membrane did not elicit a maximal allergic reaction, an experimental finding similar to that which had been noted in connection with the passively sensitized nasal mucous membrane.²² The fact that blood-borne antigen, even though diluted, was able to elicit more intense allergic responses than concentrated antigen applied directly to the epithelial surface tends to minimize the importance of the latter as a shock tissue.

OTHER ABDOMINAL ORGANS AND TISSUES SHARING IN ALLERGIC REACTIONS

In the histologic studies of the allergic abdominal organs, it was repeatedly noted that the peritoneum shared in the inflammatory reactions. When the sensitizing sera were introduced into the serosa of the intestine, the allergic reaction, subsequently elicited, was most pronounced in the peritoneal layer.¹³ The edema, in such an instance, tended to surround the gut and to affect the muscular and mucosal layers only to a slight degree. Frequently, the edema spread between the layers of the mesentery, increasing its thickness considerably. An increase of secretion was definitely noticeable over the affected serosa. It was also of interest to note that, when the peritoneum was the seat of the allergic reaction, tonic spasm of the bowel in this region was not commonly observed as it had been when the mucous membranes had been sensitized. All these findings suggest that the peritoneum itself may be the primary seat of an allergic reaction and that allergic peritonitis should be recognized as a possible cause of abdominal disturbances in allergic individuals.

Allergic cholecystitis is another clinical possibility which is not being given sufficient consideration in the differential diagnosis of pain in the right upper quadrant in allergic individuals. Experiments in the monkey, demonstrating that this organ can be sensitized, and the pathology of the allergic reaction occurring in the gall bladder have already been presented.¹³ Allergic involvement of the gall bladder may possibly account for the frequent failure to find roentgenographic evidence of gall bladder disease in allergic patients with the typical symptoms of cholecystitis. Moreover, the transient nature of the inflammatory process in allergy may account for the absence of pathology in the gall bladder by the time these patients reach the operating table after a protracted period of observation and preparation. The diagnosis, however, may be established by the fact that the feeding of the specific allergen induces gall bladder symptoms at will, while its elimination from the diet produces a complete cessation of symptoms.

Attempts to demonstrate sensitization of other abdominal organs and tissues have met with only partial success.¹³ The allergic reaction in the sensitized spleen in the monkey was a brief one. Following intravenous administration of the offending antigen, the spleen swelled rapidly and assumed a darker color. The process was only short-lived, however, and the organ returned to its normal state within a few minutes.

The allergic reaction in the passively sensitized uterus¹³ appeared, for the most part, to involve the peritoneum and subperitoneal connective tissue. The uterine muscle and endometrium seemed hardly to share in the edema.

Injection of the reagin-bearing serum into a lobe of the liver did not induce sensitization of hepatic tissue, and no evidence of an allergic reaction in this organ has thus far been obtained.¹³ Attempts at sensitization of renal tissue have invariably resulted in death of the animal before the experiment could be completed.

DISCUSSION

Although the reagin mechanism has been used to reproduce experimentally the allergic reactions in the various abdominal tissues and organs, it is not my intention to suggest that all allergic reactions are mediated by this antibody. It is, in fact, common knowledge that food hypersensitiveness occurs in the absence of reagins and, therefore, of positive cutaneous reactions to the offending allergen. In such instances, the clinician is compelled to rely on clinical trials and diets for the diagnosis. A close scrutiny of the patient's daily food diary and analysis of his symptoms in relation to each article of his diet may be necessary for the detection of the offending allergen. Coca²³ has recently suggested pulse rate studies as a means of diagnosis in nonreaginic food allergies.

Regardless of the absence of reagins in many forms of food hypersensitiveness, their use in the above investigations has yielded some definite experimental information as to the nature of the processes involved in abdominal allergy and opens the way for still further investigation of this little explored field.

CLINICAL AND EXPERIMENTAL

FAMILIAL NONREAGINIC FOOD ALLERGY*

ITS SPECIFIC DIAGNOSIS AND TREATMENT

ARTHUR F. COCA, M.D., ORADELL, N. J.

IN TWO previous informal publications^{1, 2} it was stated that certain allergic clinical reactions to foods were so constantly accompanied by tachycardia that in all the few cases that had been observed the offending foods could be identified through the use of that objective criterion.

This observation seemed especially welcome because the usual cutaneous tests for food sensitivity failed in nearly all the cases studied—as they have in nearly all the 19 succeeding ones that were so tested.

The findings were reported informally because the cases seemed too few to be acceptable in the usual media of publication, and yet interesting enough to suggest a further trial of the method of diagnosis in suitable cases.

More recently, additional cases have become available for study, and it is now evident that another category of familial allergic disease must be recognized as quite distinct from the previously recognized atopic group of bronchial asthma, hay fever, and atopic dermatitis. Briefly, the separation of the two categories is required on account of (1) differences in symptomatology; (2) difference in mechanism; and (3) difference in the hereditary factor. Only the first two differences will be discussed in the present report. However, the two terms that have been tentatively chosen to designate the two categories will be used for convenience in this paper. These are *atopy* (reaginic asthma, hay fever, atopic dermatitis) and *familial nonreaginic food allergy* (urticaria, allergic headache—migraine, gastrointestinal food allergy, and a number of other more or less serious clinical manifestations).

This investigation has already taken several different directions, detailed mention of all of which cannot be made in a single report of this kind. It is intended, in this first paper, to present evidence to indicate: (1) that specific tachycardia is a reliable criterion of nonreaginic food-allergic reaction; (2) that this criterion can be practically employed with a high percentage of success in the complete relief of food-allergic symptoms.

The eight charts presented are examples of transient tachycardia in some of which there is a close association with the ingestion of a particular food and with one or more clinical symptoms of food allergy.

In these graphic records of the pulse rate in four of the 31 persons who have been relieved of their food-allergic symptoms under the regime of trial diet that

*From Lederle Laboratories, Inc., Pearl River, N. Y.
Received for publication, July 18, 1940.

has been described elsewhere,^{1, 2} three characteristic phenomena are illustrated: (1) the rapidly alternating tachycardia and remission of the high pulse rate; (2) the latent period of the food-allergic reaction, and (3) the recurrent reaction.

The patient referred to in Chart 1 is a particularly interesting object of study because she was subject to paternally inherited atopic asthma and hay fever (pollen, house dust, wheat), as well as to the nonreaginic food allergy which she inherited from her mother. Ingestion of wheat, especially possum, causes an attack of asthma but no tachycardia, and her serum passively sensitizes the normal human skin, markedly to house dust and distinctly, though not markedly, to wheat. On the other hand, potato, pork, orange, and coffee, all cause tachycardia, headache, and other clinical symptoms of nonreaginic food allergy (Table I), but the patient's serum does not passively sensitize the normal human skin to these four foods.

Chart 1.—The course of the pulse rate in patient M. M. D. on the sixth to the twentieth day of observation.

This demonstrated coincidental occurrence of the reaginic atopy and the nonreaginic food allergy in the same person suggests the possibility that the two forms occasionally may be exhibited by the same person to the same food. Hence, it will not be necessary, if, in the blood of a patient with migraine (for example), atopic reagins should be demonstrated that are specific for an excitant of it, to conclude that the reagins in that instance represent the specific mechanism of the migrainous attack.

The following additional features of this case are of interest:

(1) Beef, puffed wheat, or bread, milk, and twice ultrafiltered lemon juice were taken throughout the period indicated in Chart 1.

(2) Although potato was discontinued after lunch on the eighth day, the pulse rate rose twice on the ninth day. This recurrence of symptoms after discontinuance of an allergenic food is also illustrated in the record of the pulse rate after the ingestion of orange by this patient. There was mild recurrence of tachycardia and also symptoms (headache) on the second day after the discontinuance of orange.

(3) Orange was taken in liberal quantity at all three meals for nearly two days before symptoms appeared. This was the first observed instance in this study of the "latent period," which presently will be discussed more fully.

(4) The causes of the brief but considerable acceleration of the pulse rate on the twelfth day were not discovered. There may have been an accidental addition of some unsuspected allergen in the diet on that day.

(5) The level line at 80 indicates the highest recorded pulse rate (observed before and after each meal) during the indicated period. The pulse rate was frequently lower—sometimes as low as 72.

(6) Tachycardia was sometimes present for an appreciable time after the other symptoms had disappeared. In another person noticeable tachycardia has frequently been absent when the patient was suffering severe heartburn due to ingestion of relatively small quantities of an allergen.

Chart 2.—The course of the pulse rate in patient A. R. on three days previous to the period of trial diet, and on the first five days of the trial diet.

Chart 3.—The course of the pulse rate in patient A. R. on the sixteenth to the thirtieth days of observation.

A young biological chemist, A. R., whose pulse record is illustrated in Charts 2 and 3, had since February, 1939, been suffering from the symptoms mentioned in Chart 2 and had lost 25 pounds in weight. The pulse record shown under the figures 1 to 4, representing the first four days, shows the range of the pulse rate over 84 (which was found later to be his normal maximum) on his usual diet, which included generous amounts of milk and bread. On the fifth and sixth days, and on the morning of the seventh day, he took only milk every hour, and became convinced, at the end of this trial, that milk does not agree with him. He changed to a pure

egg diet from lunch on the seventh day and his symptoms lessened, the pulse rate on the eighth day showing a slight recurrent reaction to milk. After the ninth-day period he added wheat, beet sugar, and pork to his diet without experiencing symptoms, his pulse remaining under 84.

Following the ingestion of a yeast-raised zwieback, his symptoms recurred with a mild tachycardia. On the sixteenth and seventeenth days, he took several cakes of Fleischmann's yeast and, after a latent period of about a half day, experienced clinical symptoms with tachycardia. On the eighteenth day his pulse registered a slight, recurrent reaction. During the period between the nineteenth and thirtieth days, in which other foods were added to the diet, he was symptom free. The thirtieth day he spent in New York City where, as he reported, he "became overexcited and fatigued by climbing subway and elevated steps"; he ascribed to this unusual experience the headache and tachycardia recorded on that day. However, inquiry revealed that at lunch he had eaten omelet, not being aware of the milk content of this dish. He has been symptom free during the succeeding eighteen months and has gained 35 pounds in weight.

Chart 4.—The course of the pulse rate in patient J. G. on three days prior to the period of trial diet.

Trials with 30 different foods have revealed no other sensitivities.

The serum of this patient does not cause the slightest detectable passive sensitization of the human skin to milk.

J. G., a 36-year-old man, active in the management of a large city gauge, complained chiefly of a headache on the left side which recurred at one- to two-week intervals and incapacitated him for about three days. The recurrent headaches were of eighteen years' duration, and the most serious step in his previous treatment of them had been an exploratory abdominal operation performed at his insistence. Charts 4 and 5 show the course of his pulse rate in the first three days on a general diet, and in the first five days of the "trial diet."

It is seen in Chart 4 that his maximal pulse rate in the three days previous to the beginning of treatment was not very high—86. However, on an exclusive diet of beef on the fifth day, and of beef and milk on the sixth day (Chart 5), the pulse rate did not pass above 74. Following the addition of wheat on the seventh day the maximal rate reached 90, and he had a headache. He took no wheat after the evening meal of the seventh day, and there

Chart 5.—The course of the pulse rate in patient J. G. on the first five days of the trial diet.

Chart 6.—The course of the pulse rate in patient C. T. on three days prior to the period of trial diet. B, breakfast; L, lunch; D, dinner.

were no symptoms thereafter. There was a vigorous recurrent tachycardia on the eighth day and a milder one on the ninth. The subsequent trial of coffee caused hives, but no headache. Cane sugar caused headache without hives. This patient has made trials of at least twenty-four other foods, with no unexplained clinical symptoms nor tachycardia in the succeeding twelve months.

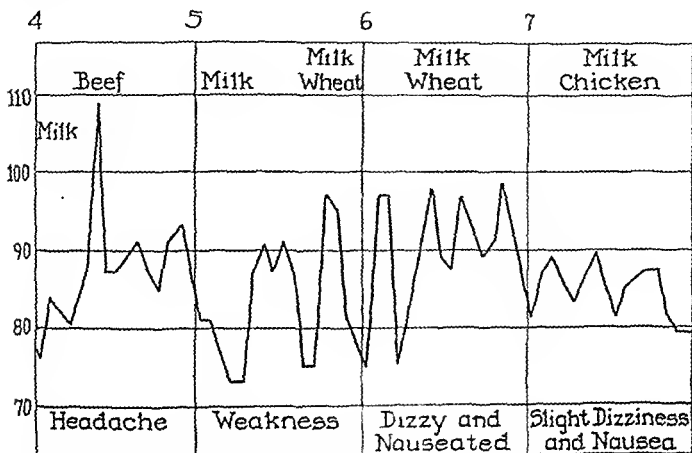

Chart 7.—The course of the pulse rate in patient C. T. on the first four days of the trial diet.

Chart 8.—The course of the pulse rate in patient C. T. on the second four-day period of the trial diet.

The cutaneous tests with the common inhalants and foods, including wheat and coffee (scratch tests with strong glycerinated extracts), were negative.

The record of the pulse rate in a young woman, C. T., employed by a large life insurance company in New York City, is shown in Charts 6, 7, and 8.

TABLE I

PATIENT	AGE	SYMPTOMS	RANGE OF PULSE RATE		TREATMENT BEGAN	ALLERGENIC FOODS
			BEFORE TREATMENT	AFTER TREATMENT		
E. F. C.	49	Migraine, mucous colitis, dizziness, neuralgia, nervousness, abdominal pain, physical tiredness, canker sores, intestinal bleeding, nausea, vomiting, "extrasyctoles," angina pectoris	Up to 180	68 to 84	Aug. 1935	Beef, lamb, fish, egg, milk, cereals, string beans, Lima beans, white potato, sweet potato, tomato, onion, artichoke, squash, cabbage family, lettuce, carrot, beet, spinach, turnip family, nuts, plum, pear, melon, pineapple, peach, banana, apricot, asparagus, parsnip, pepper, coffee, pork, orange
A. F. C.	65	Migraine, gastric pain (cramplike), abdominal pain, pain in region of gall bladder, heartburn, canker sores, severe dizziness, physical tiredness, gastrointestinal bleeding, extrasyctoles, psychic depression, nervousness, chronic rhinitis, constipation, neuralgia, conjunctivitis	56 to 100	58 to 72	Aug. 1935	Pork, fish, cereals, cane sugar, white potato, sweet potato, beet, carrot, spinach, peas, beans (string and Lima), cabbage family, lettuce, asparagus, parsnip, artichoke, turnip family, tomato, mushroom, maple sugar, chocolate, apple, olive, date, nuts, yeast, squash, pineapple, plum, peach, apricot, melon, orange, grapefruit, lemon, onions, grapes, pepper, coffee, tea, aluminum, fowl, cow's milk, banana
M. M. D.	27	Migraine, nausea, chest pain, marked physical tiredness, nervousness, vomiting, canker sores, constipation, bronchial asthma	70 to 100	70 to 80	Jan. 1936	Pork, potato, orange, coffee
A. R.	28	Migraine, nervousness, chest pain, heartburn, dizziness, extrasyctoles, neuralgia	66 to 108	70 to 84	Aug. 1939	Milk, yeast
G. T.	26	Nausea, diarrhea, neuralgia, extrasyctoles ("fluttery heart"), marked physical tiredness, canker sores, marked dizziness, psychic depression, constipation, "nervous and emotional instability—incurable"	65 to 112	72 to 78	Jan. 1940	Beef, cereals, cane sugar, orange, tomato, prune, grapefruit, potato, pineapple, onion, banana, strawberry, egg, lemon
J. G.	36	Incapacitating 3-day headaches at 1- to 2-week intervals; frequent urticaria and angioneurotic edema, heartburn	66 to 86	66 to 80	Jan. 1940	Wheat, sugar cane, coffee
H. E.	49	Dizziness, migraine, "gas," physical tiredness, anorexia	76 to 106	58 to 76	March 1940	Wheat, milk, coffee

W. W. F.	57	Headaches, heartburn, "indigestion," canker sores, marked physical tiredness, petit mal (frequent during past 20 years); epileptic sib	66 to 100	56 to 68	April 1940	Beef, orange, lamb
M. W. F.	52	Headaches, heartburn, "gas," indigestion, nervousness, marked physical tiredness	72 to 100	58 to 72	April 1940	Criseo, peanut, cinnamon, pecan
A. W. F.	17	Allergic sore throat	70 to 90	60 to 72	April 1940	Chocolate
F. C. F.	16	Severe headaches, dizziness, physical tiredness	58 to 84	58 to 70	April 1940	Chocolate, criseo
M. B.	22	Frequent spontaneous epistaxis	64 to 100	64 to 76	April 1940	Egg
P. W.	47	Constant severe headache, dizziness, marked physical tiredness, chronic rhinitis, post-nasal drip, bronchial asthma ("infectious")	68 to 100	62 to 78	April 1940	Beef, lamb, egg, cow's milk
R. M.	22	Frequent severe headaches, dizziness, nervousness, canker sores, "indigestion," constipation, marked dysmenorrhea	68 to 100	62 to 78	May 1940	Beef, egg, potato, tomato, chocolate, coffee
A. P.	70	Marked generalized urticaria (dollar size), chronic cough, constipation	72 to 100	70 to 74	May 1940	Beef, cow's milk, egg, yeast, olive, corn, banana, proprietary laxative
S. I. H.	40	Frequent headaches	68 to 100	64 to 80	June 1940	Beef, lamb, white potato, tomato, orange, yeast, sugar cane
H. A. S.	58	Marked urticaria at long intervals, occasional headaches, canker sores, neuralgia, physical tiredness	60 to 105	60 to 74	June 1940	Beef, bean, asparagus, chocolate, corn, Swiss chard, peas, cinnamon, eggplant, coffee
J. F.	53	Headaches, angioneurotic edema, physical tiredness, chronic rhinitis, postnasal drip of 10 years' duration, constipation	68 to 108	68 to 80	June 1940	Lamb, egg, chicken, potato, tomato, grapefruit, chocolate, coffee, tea, orange
W. S. C.	41	Headaches, "indigestion," gas, nervousness, marked physical tiredness	46 to 70	46 to 62	July 1940	Beef, potato, cow's milk, tobacco
J. V.	35	Headaches (almost continual, incapacitating), asthma (mild), physical tiredness, chronic rhinitis	44 to 78	48 to 64	July 1940	Cow's milk, wheat, carrot, tomato, lettuce, banana, melon, lemon, peanuts, egg, peach, cereals, cabbage family, bacon, ham, pear, peppermint

TABLE I—CONT'D

PATIENT	AGE	SYMPTOMS	RANGE OF PULSE RATE		TREATMENT BEGAN	ALLERGENIC FOODS
			BEFORE TREATMENT	AFTER TREATMENT		
E. B.	50	Constant headache, nervousness, neuralgia; "very irritable," marked physical tiredness	82 to 108	72 to 76	July 1940	Wheat, pork
Dr. R.	26	Severe incapacitating headaches, physical tiredness, chronic rhinitis, dizziness, neuralgia, heartburn	70 to 90	70 to 76	Aug. 1940	Milk (cow's), egg, orange, grapefruit
R. F.	34	Severe headache (left side), heartburn, neuralgia, physical tiredness, nervousness, chronic rhinitis	64 to 114	62 to 76	Sept. 1940	Fowl, milk (cow's), wheat, corn, nuts, plum (prune)
A. F.	10	Headaches, bronchial asthma	82 to 124	74 to 78	Oct. 1940	Milk, beef, pork, squash, grape, peas, lettuce, tomato, cabbage family, celery, orange, peanut, marshmallow
N. W.	38	Severe headaches, indigestion, heartburn, canker sores, dizziness, physical tiredness, neuralgia, chronic rhinitis, nervousness	64 to 86	62 to 76	Nov. 1940	Pork, potato, sweet potato, tomato, pear, beef, cabbage family, peas, string beans, mushrooms
Dr. I. P.	46	Severe gastric pain (suspected ulcer) operation contemplated	84 to 104	72 to 78	Jan. 1941	Diagnosis incomplete Cow's milk, major allergen (if there are others they are negligible)
L. H. B.	20	Marked headaches, dizziness, physical tiredness, occasional urticaria, acne, nausea, vomiting	60 to 90	58 to 70	Jan. 1941	Wheat, chocolate, peas, onion, string bean, squash, white and sweet potatoes, spinach, rice, chicken, peach, apricot, orange, banana, tomato, grapefruit, pineapple, cabbage, carrots, lettuce, beets
J. J. V.	38	Headaches (frequent), bronchial asthma, nervousness, physical tiredness, acne, angioneurotic edema	70 to 94	62 to 74	Jan. 1941	Cow's milk, tomato, onion, potato, lamb, Lima bean, fish, oyster, tobacco, sweet potato, coffee, chocolate, orange, chicken, apple, banana, cabbage, celery
C. B.	23	Chronic rhinitis, bronchial asthma	72 to 100	67 to 72	Jan. 1941	Wheat, egg, lettuce, cane sugar
K. S.	48	Migraine, physical tiredness, constipation, nervousness, neuralgia, extrasystoles	70 to 110	70 to 80	Jan. 1941	Fish, lamb, potato, peas, string beans, carrot (tomato not tested but avoided on account of earlier experiences)
M. D. B.	Over 50	Heartburn, migratory neuralgia, constipation, physical tiredness	62 to 90	52 to 60	April 1941	Milk, orange, lemon, carrot, beet, asparagus (spinach not tested but avoided)

The outstanding symptoms in her case were recurring attacks of marked dizziness (without headache), which so interfered with her work as to make her continued employment uncertain. The company physicians had once placed her under psychiatric observation in a sanatorium for three months and had reached a diagnosis of "emotional and nervous instability" which they considered incurable. She consulted me only to inquire why she was always decidedly worse immediately after injections of "cold vaccine." At that time, under the threat of losing her position, and because her life was otherwise intolerable, she was contemplating suicide.

Since it was imperative that she be kept from her work not longer than ten days, more rapid additions to the diet were allowed than is usually advisable. The headache caused by beef (taken three times) was the first severe headache in her experience.

The first rise of the pulse rate on the fifth day was interpreted as recurrent from the reaction to beef; the second rise on that day was thought probably to be due to wheat. The patient has been found sensitive to all other cereals and sugar cane, and to orange, grapefruit, tomato, coffee, onion, banana, pineapple, strawberry, lemon, and egg.

During the succeeding nineteen months (to date) she has, with few exceptions,* been free from the dizziness as well as all the other minor symptoms (canker sores, nausea, diarrhea, "fluttering heart," neuralgia, and marked lassitude). The exceptional episodes could all be referred to the unwitting eating of one or the other of the allergenic foods. On one occasion she ate at the evening meal only the meat of a fowl that had been stuffed with bread, and the next day she suffered a mild dizziness.

Direct intracutaneous tests with extracts of the incriminated foods gave negative results. Intracutaneously injected into a known receptive patient (E. D.) her serum in a quantity of 0.05 c.c. failed entirely to sensitize the skin passively to beef, wheat, orange, and coffee (no tests were done with the other allergenic foods).

Table I presents the essential data of the 31 persons with nonreaginic food allergy who have been successfully treated with the method of trial diet controlled through the pulse rate.† The following points may be emphasized.

The range of the food allergic pulse rate varies greatly in different persons, for example, J. G. and F. C. F. showed high rates of only 86 and 84, respectively. The range of the normal pulse rate varies greatly in different persons; the high count (68) of W. W. F. is the same as the low count of J. F.

In most cases the symptoms mentioned in Table I could be induced by eating one or the other of the allergenic foods identified by means of the tachycardia. Many of those symptoms have not been generally recognized as due to food sensitivity; especially, nervousness, dizziness, allergic sinusitis, physical tiredness ("no 'count feeling"—Vaughan) and irritability. *All of these symptoms disappeared in the respective patients after the pulse rate became normal following the elimination of the allergenic foods, and they were usually reproducible in all such persons by the mere eating of the forbidden foods.*

In one patient with food allergy (Dr. "C.") the tachycardia, although amply present (range of 64 to 84, once 90), could not be practically used in the detection of the offending foods. On the one hand, the single pulse rate of 90 was recorded on a day when the patient was "feeling quite well"; whereas, on one morning when he "awoke feeling as though an attack were impending," the pulse rate ranged between 72 and 76. However, this patient showed other peculiarities. Dr. "C.," with much difficulty using the Andresen method, has identified "meat, fish, chicken, eggs, wheat, chocolate, and coffee" as allergenic

*These will be discussed in a later publication.

†In each instance the pulse rates were noted by the patient, the figures representing the half-minute count multiplied by 2. No instructions were given the patients as to posture, etc., when the counts were being taken. This and other practical considerations will be discussed in detail in a later publication.

in his case. Yet, on one occasion after having eaten chicken liberally on three successive days (just after a four-day attack), he was "feeling quite well" on the third day—the day of the single pulse rate of ninety. By avoiding the above-mentioned foods, or eating them in the respective "latent period"—"occasionally, or once weekly"—he has reduced his attacks to "one severe one and one mild one in 5 months."

There are two possible explanations of this failure to arrive at complete relief of the allergic symptoms. (1) The patient, being a doctor of medicine was in the habit of taking certain commonly used drugs at the first premonition of an "attack." It has been seen in other cases that drugs may so affect the pulse rate as to interfere with the interpretation of the record. (2) This case was being studied long before the allergenic action of metals and essential oils had been recognized.*

There have been a few other "failures," all of which are similarly explainable.

Most of the foods that have been identified as excitants of nonreaginic food allergy in the 31 patients that have been under this kind of treatment have been common ones. Table II shows the list of these foods.

TABLE II

FOODS MOST COMMONLY INCRIMINATED AS EXCITANTS OF FAMILIAL NONREAGINIC FOOD ALLERGY IN 31 CASES

Wheat	11	White potato	8
Orange	11	Chocolate	8
Egg	11	Coffee	7
Beef	10	Sugar cane	6
Milk	10	Sweet potato	5
Tomato	9		

LATENT PERIOD IN NONREAGINIC FOOD ALLERGY

In the case of A. F. C. it had been noticed that after sensitivity to a number of vegetable foods had been unquestionably established in several separate tests, in all of which the allergenic food had been eaten in generous quantity several times over a period of one or more days, if the food was avoided for a long time it could always be eaten once, often more than once, with impunity. I began to generalize my thoughts about this recurring phenomenon after I came across the following statement by Vaughan^{3a}: "This, we shall see, is very characteristic of food allergy, that an allergenic food may be eaten at times with impunity, at other times with consequent symptoms."

The thought took a practical turn upon the following observation of J. G. (see Chart 5), who had been found sensitive to wheat. About two months after his first test with wheat, he ate, only at one meal, an unstinted quantity of bread after which he suffered no clinical symptoms and observed no rise of the pulse rate above his normal maximum.

The relatively short interval (two months) between the two tests with wheat suggested the question how short the interval can be made without the occurrence of a reaction. This question was studied in the case of A. F. C., by administering at six- or seven-day intervals a number of vegetables and fruits to all of which he had been proved sensitive. Some of these foods (peas, string beans, Lima beans, beet, date, raisin) had not been eaten for several weeks, some not for several years (asparagus, broccoli, alligator pear, celery, apple, yam, squash, endive, tomato, onion, peach, pear, prune, blueberry, raspberry, and cane sugar). With three exceptions no tachycardia or allergic symptom followed the first two ingestions of these foods.

Broccoli caused no symptoms on the first ingestion, but after the second, six days later, there was heartburn and an eight-point rise of the pulse rate from the normal maximum of

*To be discussed in a later communication.

72. Squash on the first eating caused no reaction, but one week later it caused nervousness and a tachycardia (93). Yam, eaten for the first time after an abstinence of many years, caused headache and heartburn, the latter being felt within a few hours, and the former on the following morning.

Patient A. R. (see Charts 2 and 3), after abstaining from milk for six months, has taken a glass of milk once without experiencing symptoms or tachycardia.

The latent period is illustrated in the case of M. M. D. (Chart 1), who ate oranges from dinner January 16 to lunch January 18 before headache and tachycardia (to 104) began.

There was a similar experience with oranges in the case of C. T., symptoms being delayed for nearly forty-eight hours.

In some instances in the case of A. F. C. opportunity has been had to observe that the longer the interval of abstinence from an allergenic food the longer the latent period. Thus, string beans, after having been previously avoided for a number of years, were eaten almost every day from October 3, 1939, until March 10, 1940, when symptoms and tachycardia appeared, which ceased about twenty-four hours after the last consumption of string beans. On April 13 eating of string beans was resumed, at first at four- to five-day intervals and from May 22 at seven-day intervals without symptoms until June 19, when mild headache appeared in the night, and again June 26, when abdominal pain followed soon after eating the beans. After an interval of two weeks, indulgence in a liberal quantity of the beans was followed shortly by slight intestinal discomfort. The pulse rate was 72 after walking up two flights of stairs.

Grapes and raisins had been previously avoided for about nine years, when after January 10, 1940, they were taken almost daily without symptoms, until February 12, on which date heartburn, flatus, and headache appeared. Lettuce, which was also being eaten, was discontinued on February 16, but the headaches, heartburn, and flatus continued until twenty-four hours after grapes and raisins were omitted on February 28. There were no allergic symptoms after February 29 until March 4, heartburn from rice wafers) and March 10 when headache marked the return of sensitivity to string bean.

From the foregoing data it is seen that the latent period of nonreaginic food allergy is not constant. It varies in different persons and in the same individual with respect to different foods. The latent period has been encountered in 13 of the 31 patients (E. F. C., M. M. D., C. T., J. G., W. W. F., R. M., H. A. S., J. F., W. S. C., A. R., R. F., M. D. B., I. H. B.). Most of the 13 patients are making regular practical use of the phenomenon by eating the respective allergenic foods at safe intervals.

The phenomenon of the latent period is clearly described by Vaughan,^{2a} who cites in illustration a case of sensitivity to egg with avoidance of that food "for three years." The patient, being found "negative" to the cutaneous test, resumed the eating of egg and, one month later, began again to exhibit the allergic symptom (migraine). In such a case Vaughan speaks of the allergenic food as a "build-up" food, referring to the time required, after the period of avoidance, for the re-establishment ("build up") of the sensitivity.

SIGNIFICANCE OF THE LATENT PERIOD OF NONREAGINIC FOOD ALLERGY

An interpretation of the latent period of food allergy is found in a simple description of the fact in other words; namely, the sensitivity is lost for a time, the duration of which depends probably among other things, upon the length of the period of avoidance.

One may say that in many instances continual contact with the excitants of nonreaginic food allergy is necessary for the maintenance of that kind of human allergic disease. Vaughan evidently entertains the same view of the phenomenon.

This phenomenon is seldom, if ever, observed in reaginic atopy. It is true that reaginic atopy is sometimes "outgrown" but not necessarily following avoidance. Indeed, it seems well established that the natural process of outgrowing hay fever is often expedited by artificially increasing the exposure to the excitants of it. Under the specific therapy of hay fever by injections of an extract of pollen, the reagin content of the blood diminishes in many patients after a few years of continual (perennial) treatment.⁴

Thus the "latent period" of nonreaginic food allergy stands as a mark of differentiation of this category from the atopic group.

SUMMARY

1. Evidence has been presented of an association of tachycardia with clinical symptoms of familial nonreaginic food allergy, which was so regular in the 31 cases studied that the tachycardia could be used as an objective diagnostic criterion of the allergic reaction through which the specific excitants (foods) could be identified.

2. A "latent period" of lost sensitivity has been recognized in a number of instances of food allergy. In some instances this latent period has been found to vary in duration according to the length of the period of avoidance of the respective allergenic food. The practical use of the latent period is described.

3. Some of the grounds for distinguishing two categories of familial sensitivity are discussed.

4. The occurrence of reaginic and nonreaginic sensitivity to foods in the same individual has been described, and the practical consequences of such a coincidence are discussed.

Addendum (August 25, 1941).—The editors of this JOURNAL have permitted me to withhold this note until the article was about to be printed, in order to extend the period of observation of the patients.

The clinical results can be summarized as follows:

(1) All patients, except M. B., are still under occasional observation.

(2) All patients have had voluntary and blind tests of their specific sensitivity to various (for them) allergenic foods since the completion of their course of treatment by trial diet. In some instances no tachycardia nor allergic symptom followed the test (latent period). In all the other instances there was tachycardia, usually with one or more of the listed allergic symptoms. In most cases the test did not cause *all* the allergic symptoms. Thus, C. T. sometimes suffers tiredness or leg ache without headache or dizziness; sometimes headache alone, sometimes dizziness alone, sometimes both together. These different combinations of symptoms were present on different days under test with a single allergenic food (cane sugar). All symptoms disappeared after that food was eliminated from the diet.

(3) No unexplained allergic symptoms have occurred in any of the patients that have remained under observation.

(4) Some of the patients frequently retest themselves or deliberately "indulge" themselves if the resulting symptoms are not incapacitating; they are able to control their earlier neurasthenia, knowing the cause of each allergic episode.

(5) In some instances one or more of the symptoms that had been exhibited previous to the dietary treatment did not recur at any of the subsequent tests. For example, the monthly petit mal seizures of patient W. C. F. have not recurred once since April, 1940, although beef has been eaten occasionally, causing a moderate tachycardia.

The foregoing summary is, in a sense, an understatement; scientific language does not lend itself to the faithful portrayal of the great improvement described by many of these patients in the state of their "general health," in their sense of "well-being," in their

outlook on life, and in their behavior toward their associates. Of the great importance of these imponderables I am convinced.

Further clinical details of these cases and additional cases, as well as a detailed description of the method of treatment, will be published in a forthcoming monographic report (C. C. Thomas, Springfield, Ill.).

LEFT VENTRICULAR FAILURE DUE TO ESSENTIAL HYPERTENSION*

NATHAN FLAXMAN, M.D., CHICAGO, ILL.

THE most common forms of circulatory failure encountered in the office of the general practitioner are those in which the onset is with failure of the left side of the heart.¹ Failure of the left ventricle results from diseases in which the work of the chamber is increased or its muscle is diseased, and includes such causes as essential and nephritic hypertension, arteriosclerosis, and syphilitic disease involving the orifices of the coronary arteries to the left ventricle, defects of the aortic valve, and mitral disease with predominant regurgitation. Essential hypertension is the most common etiologic factor in the causes of organic heart disease,² and probably accounts for the greatest number of cases of isolated left ventricular failure.

Except as described by Hope,³ the concept of isolated failure of the left ventricle of the heart is one that has arisen within recent years.⁴⁻⁶ White⁶ stated that failure of the left ventricle is more common and important than that of the right ventricle and should be looked for zealously, since by early recognition and proper treatment not only may heart failure of the left side be relieved, but heart failure of the right side, which is likely to follow, may be prevented or postponed.

In a previous study on the types of hypertensive heart failure⁷ in 594 patients it was found that isolated failure of the left ventricle occurred in 156 (26.5 per cent) of the cases. These patients had no signs of systemic congestion. The mortality was lower than among those with combined ventricular failure, and the leading cause of death was not the usual congestive heart failure.

The present clinical study comprised 190 patients with isolated failure of the left ventricle due to uncomplicated essential hypertension. It included 150

*From the Department of Medicine, Loyola University School of Medicine, Chicago.
Received for publication, July 18, 1940

males (79 per cent) and 40 females (21 per cent), whose ages varied from 35 to 77 years at the time of onset of the cardiac symptoms (Table I). Of this group 70.5 per cent were in the 40 to 60 year age group, the so-called "hypertensive age." In a previous study of all types of hypertensive heart disease, 78.8 per cent were in this age group.⁸

TABLE I
PERCENTAGE OF THE AGE GROUPS AT THE ONSET

AGES	MALE	FEMALE	TOTAL	PER CENT
31-40	2	7	9	4.7
41-50	42	13	55	28.9
51-60	67	13	79	41.6
61-70	36	6	42	22.2
71-80	4	1	5	2.6
Totals	150	40	190	100.0

Symptoms which indicated the onset of failure of the left ventricle were dyspnea, cardiac pain (precordial or epigastric or both), weakness, and palpitation. Cardiac pain was a solitary complaint of 20 (10.5 per cent) of the 190 patients, but in all others the cardiac pain, weakness, and palpitation were associated with dyspnea (Table II). White⁶ indicated several important symptoms and signs that point to weakness and failure of the left ventricle, which, he contended, should permit its recognition in the absence of mitral stenosis and congenital heart disease: They are (1) cardiac dyspnea, (2) cardiac asthma or acute pulmonary edema, (3) diminishing vital capacity due to heart disease, (4) engorgement of the roentgen shadows of the lung hilus blood vessels, (5) protodiastolic gallop rhythm at the apex in the absence of heart block, (6) pulsus alternans, and (7) increasing accentuation of the pulmonary second heart sound. Of these seven points the symptoms of dyspnea and cardiac asthma, and the signs of acute pulmonary edema, were the most reliable and helpful in the diagnosis of failure of the left ventricle due to essential hypertension.

TABLE II
FREQUENCY OF THE IMPORTANT SYMPTOMS AND THEIR DURATION

DURATION	DYSPNEA AND CARDIAC PAIN	DYSPNEA	CARDIAC PAIN	DYSPNEA AND WEAKNESS	DYSPNEA AND PALPITATION
1 day to 6 months	50	34	18	7	3
7 months to 1 year	14	6	0	3	3
2 to 5 years	22	14	2	2	3
6 to 10 years	3	6	0	0	0
Totals	89	60	20	12	9
Percentage	46.8%	31.6%	10.5%	6.3%	4.8%

Combined dyspnea and cardiac pain were the most common complaints (46.8 per cent) at the onset of failure of the left ventricle. The mortality was lower among these patients than among those who had the same complaints on the basis of combined failure of both ventricles. The lowest mortality occurred among those who complained solely of dyspnea (31.6 per cent) or of cardiac pain alone (10.5 per cent). Among these patients the mortality was only 13 per cent. Thus the importance of recognizing failure of the left ventricle early,

as either dyspnea or cardiac pain, alone or combined, are the most important symptoms, cannot be overemphasized from the standpoint of attempting to reduce the immediate mortality.

The duration of the failure of the left ventricle, from the onset of the first cardiac symptoms, was estimated in 44 (23.1 per cent) known deceased patients (Table III). Data on 146 (76.9 per cent) living patients were added for comparison. Of the deceased 83.8 per cent died within two years after the onset of cardiac symptoms. The percentage of patients still living, who were observed within two years after the onset of symptoms, was 80.7 per cent, approximately the same ratio.

TABLE III
DURATION OF DISEASE AFTER ONSET OF CARDIAC SYMPTOMS

DURATION	DEAD				LIVING			
	M.	F.	TOTAL	%	M.	F.	TOTAL	%
1 day to 6 months	25	3	28	63.6	61	17	78	53.5
7 months to 1 year	4	1	5	11.4	19	6	25	17.1
2 to 5 years	6	3	9	20.4	28	3	31	21.2
6 to 10 years	2	0	2	4.6	5	7	12	8.2
Totals	37	7	44	100.0	113	33	146	100.0
Percentage	23.1%				76.9%			

Table IV indicates the age at death of these patients; 72.9 per cent died between 40 and 60 years, the "hypertensive age." In the same age period 76.6 per cent of the entire group with hypertensive heart disease⁸ died, which was about the same proportion.

TABLE IV
PERCENTAGE OF THE AGE GROUPS AT DEATH

AGES	MALE	FEMALE	TOTAL	PER CENT
31-40	—	1	1	2.2
41-50	9	1	10	22.9
51-60	19	3	22	50.0
61-70	8	1	9	20.4
71-80	1	1	2	4.5
Totals	37	7	44	100.0

CONGESTIVE HEART FAILURE

In general, congestive heart failure was the cause of death in 65 per cent of deceased patients with hypertensive heart disease.⁸ Among those with isolated failure of the left ventricle the common cause of death was equally divided between coronary thrombosis and congestive failure (Table V). Among 159 cases of hypertensive heart disease with established auricular fibrillation, congestive failure caused 85 per cent of the deaths,⁹ in 36 cases with bundle branch block, it was the cause of death in 97.2 per cent of the deceased;¹⁰ and among 127 patients with hypertensive heart with gross arteriosclerosis, it was the cause of death in 72 per cent of the deceased.¹¹ Since death occurred in only 16 (8.4 per cent) of the 190 cases during the period of observation, congestive heart failure could not be considered a common termination in these patients with isolated failure of the left ventricle. However, it was the cause of death, within six months of the onset, in each of the 16 patients.

TABLE V

PERCENTAGE OF THE CAUSES OF DEATH IN 44 PATIENTS

CAUSE	MALE	FEMALE	TOTAL	PER CENT
1. Coronary occlusion	15	1	16	36.4
2. Congestive heart failure	11	5	16	36.4
3. Uremia	6	0	6	13.6
4. Cerebral hemorrhage	5	1	6	13.6
Totals	37	7	44	100.0

Five illustrative cases are presented to demonstrate that in the absence of any irregular rhythms, complications, or advanced coronary arterial disease, and in spite of treatment, a certain small number of patients with failure of the left ventricle due to essential hypertension died from congestive heart failure.

CASE REPORTS

Patient 1. F. P., a 54-year-old white female, was known to have had hypertension and diabetes for six years. Her blood pressure was systolic 200 and diastolic 100, and the transverse diameter of her heart was 14 cm. at the onset of the first attack of acute failure of the left ventricle fifteen days before her death. In spite of bed rest and adequate doses of digitalis and diuretics, she died of congestive heart failure. Autopsy revealed only a moderately hypertrophied heart, which weighed 490 Gm., hyperemia and edema of the lungs, and cloudy swelling of the myocardium.

Patient 2. H. D., a 54-year-old white male, was known to have had hypertension for five years. At the onset of acute failure of the left ventricle five days before his death the blood pressure was systolic 292 and diastolic 154. There were crepitant râles at both lung bases, and the transverse diameter of his heart was 19 cm. The liver was not palpable and no edema was noted. Following bed rest, and the administration of digitalis and diuretics, no improvement was noted. Five days after the onset he died suddenly. Autopsy revealed a marked hypertrophy of the heart, which weighed 720 Gm., and mild sclerosis of the coronary arteries with occasional fatty and calcified plaques. There was marked edema of the lungs and passive congestion of the liver and spleen. Death was apparently due to congestive heart failure.

Patient 3. A. F., a 56-year-old white male, complained of dyspnea and weakness of three weeks' duration. He had had hypertension for one year. His blood pressure was systolic 210 and diastolic 160. Crepitant râles were present at the bases of both lungs, and the transverse diameter of his heart was 20 cm. After ten days of bed rest, digitalis, and diuretics, he failed to improve. When seen again six weeks later, his blood pressure was systolic 240 and diastolic 160, congestive heart failure was present and persisted until his death within three months. He lived five and one-half months after the onset of isolated failure of the left ventricle. The cause of death was congestive heart failure.

Patient 4. P. D., a 55-year-old white male, known to have had hypertension for four years, complained of dyspnea and precordial pain of five months' span. His blood pressure was systolic 210 and diastolic 160, and the transverse diameter of his heart was 18 cm. The liver was not palpable and no edema was noted. After bed rest and treatment with digitalis he became ambulatory in two weeks. Two months later, in spite of continued digitalis medication, he developed congestive heart failure and died within ten days. Death occurred eight months after the onset of isolated failure of the left ventricle. Congestive heart failure was the cause of death.

Patient 5. R. M., a 58-year-old white male, complained of dyspnea and weakness for eight months. His blood pressure was systolic 250 and diastolic 130, and the transverse diameter of his heart was 19 cm. The liver was not palpable and no edema was noted. His condition did not improve after bed rest, and the administration of digitalis and diuretics. Death occurred eight months and three weeks after the onset of isolated failure of the left ventricle, and was due to congestive heart failure.

CORONARY THROMBOSIS

As a cause of death coronary thrombosis or occlusion was common among the 190 patients with failure of the left ventricle, very common, one might add, as compared with the other groups of patients with hypertension. In general, it occurred as the cause of death in 10 per cent of all deceased hypertensive patients.⁸ Among those with established auricular fibrillation it was noted in only one case (2.8 per cent).⁹ In the cases with bundle branch block it did not occur at all.¹⁰ And among those who had hypertension with gross arteriosclerosis, where coronary occlusion was common, it was the cause of death in only 6.6 per cent of those who died.¹¹

Coronary thrombosis appears to be the important factor in failure of the left ventricle due to essential hypertension. It was the leading additional factor (8.5 per cent) in 190 patients (Table VI). During the course of hypertensive heart disease⁸ it occurred as an additional factor in 6 per cent of the patients; in those with auricular fibrillation⁹ it was noted in only three (1.9 per cent) of the 158 patients; and only one patient (2.7 per cent) with bundle branch block¹⁰ had coronary occlusion. However, in persons with hypertensive heart disease with gross arteriosclerosis, coronary occlusion was more common, since it occurred among 9.5 per cent of 127 patients.¹¹ This was to be expected since the patients in the latter group were older, 84 per cent were over 60 years, and sclerosis of the coronary arteries was the rule rather than the exception.

TABLE VI
ADDITIONAL FACTORS IN 190 PATIENTS

CONDITION	MALE	FEMALE	TOTAL	PER CENT
1. Coronary occlusion	13	3	16	8.5
2. Angina pectoris	10	2	12	6.3
3. Cerebral hemorrhage	9	2	11	5.8
4. Diabetes mellitus	1	4	5	2.6

Cases of isolated failure of the left ventricle with regular rhythm, where death occurred due to the coronary factor, are added to emphasize and illustrate the facts mentioned.

CASE REPORTS

Patient 1. M. W., a 54-year-old white male, had attacks of pain localized strictly to the precordial area for six months. These attacks increased in frequency, and gradually he became short of breath. When he was first examined eleven days before his death, his blood pressure was systolic 190 and diastolic 140. Crepitant râles were heard at the bases of both lungs. The transverse diameter of the heart was 17 cm. The liver was not palpable and no edema was noted. Following bed rest and treatment with digitalis, his condition improved, but on the eleventh day he suffered a typical attack of acute coronary thrombosis. His blood pressure dropped to systolic 146 and diastolic 92, and he died on the same day. An autopsy revealed severe coronary sclerosis, with marked narrowing of the coronary lumen. There was a recent thrombus occluding the left descending branch of the coronary artery at the site of an atheromatous ulcer and a recent myoinfarction in the anterior wall of the left ventricle. The heart weighed 720 Gm. and was markedly hypertrophied. This was a definite case of isolated failure of the left ventricle on the basis of essential hypertension. Death was due to coronary thrombosis while the patient was under treatment and showed marked improvement.

HIGH INCIDENCE OF INFECTIVE STOOLS IN A SMALL OUTBREAK OF INFANTILE PARALYSIS*

GEORGE Y. McCLURE, M.D., ALBANY, N. Y.

THIS paper is an account of work done on the stools of patients suffering from, or suspected of having, anterior poliomyelitis. The techniques used are based essentially on those developed by Trask, Vignee, and Paul,¹ and by Kramer and his co-workers,² but are modified somewhat to suit our purposes.

Stool specimens were received at the laboratory in 25 ml. sterile glass containers with metal screw tops, or in 250 ml. bacteriologic water bottles with ground-glass stoppers. No reagents were added to the specimens before they arrived at the laboratory. On receipt from 20 to 25 ml. were suspended in from 90 to 100 ml. of sterile distilled water in a wide-mouthed bottle with a ground-glass stopper. To this about 15 ml. of ethyl ether were added. The suspension was then shaken by hand for from five to ten minutes and placed in the refrigerator at a temperature of from 4° to 10° C. After twenty-four hours cultures were made on horse blood agar plates and incubated for twenty-four hours. If these plates showed only slight growth, and no streptococci were present, the suspension was evaporated under vacuum in a desiccator containing sulfuric acid to get rid of the ether. Three mice were inoculated intraperitoneally, each with 0.1 ml. of the suspension. If the mice survived twenty-four hours, it was considered safe to proceed with monkey inoculations. If the mice died, the specimen was treated again with ether, and the whole procedure was repeated. Usually two treatments were sufficient, although before the use of mouse controls two monkeys in the first series died of peritonitis from the lesions of which presumably pathogenic microorganisms were isolated.

Because of these deaths an attempt was made at first to get a better bactericidal agent by using vinyl ether, and also chloroform, but without success; and lastly by shaking the suspension from two to four hours in a shaking machine with ethyl ether. This last procedure sterilized the stools more effectively, but most of them proved to be toxic. The test mice consistently died within ten hours, and only slight bacterial growth was obtained from the peritoneum. Monkeys inoculated with such stools evidenced a severe and rapid toxemia with subnormal temperatures and evidence of paralytic ileus. Two of them died within twenty-four hours, and no microorganisms were isolated either from the peritoneum or from the heart's blood. Moreover, no monkey inoculated with material treated in this manner developed poliomyelitis. We eventually returned to our original method with such success as will be pointed out subsequently.

*From the Division of Laboratories and Research, New York State Department of Health Albany.

Received for publication, July 23, 1940.

The stool inoculations in all cases were made intraperitoneally, from 5 to 20 ml. being given at an injection. Occasionally with two injections on successive days, as much as 30 ml. were given. Stool suspensions shaken only briefly with ether invariably settled out into layers. Upon injection the topmost, clearest layer and some of the middle, cloudier material were taken. The coarse sediment at the bottom of the bottle was not disturbed.

For monkey passage we used rather heavy 10 to 20 per cent suspensions of supposedly infected brain and spinal cord material, ground in the beginning with pulverized glass, but recently with aluminum, and suspended in physiologic salt solution. The suspension was centrifuged at about 2,000 r.p.m. for ten minutes. Routinely 1.0 ml. of the supernatant was inoculated into the left frontal lobe, and 5.0 ml. were inoculated intraperitoneally. In each case, four immature mice were inoculated intracranially and intraperitoneally with the same suspensions. None of the mice at any time showed signs of disease.

The first group of patients consisted of four children with clinical poliomyelitis, and an adult believed to be suffering from a second attack of the disease. All were inmates of an institution and were convalescent. The cases were studied during April, 1939, through the courtesy of Dr. A. C. Silverman of the City Hospital, Syracuse, N. Y. The stool specimens were treated as described, with only slight shaking. Specimens from the four children proved infective for monkeys, and second or third passages were obtained. The animal inoculated with the specimen from the adult remained alive and well. Table I shows the relationships between the clinical disease and the collection of stools. It is of interest that in the case of S. C. a period of ten days elapsed between the probable onset of the disease and the collection of stool material. It is also of interest that all of these children, and another to be noted later, were under two years of age. All had flaccid paralysis of some degree, four in the extremities and one in the face.

The next group of cases studied was from a small outbreak near Germantown, N. Y., in August, 1939, investigated with the help of Dr. L. D. Carpenter. Stool specimens were obtained: one from a child with extensive paralysis in the first week of the disease, and another from a collateral contact who had had a brief febrile illness at about the same time but without paralysis. We were unable to produce poliomyelitis in monkeys, and one of three animals inoculated died of peritonitis; hemolytic streptococci were isolated.

With the cooperation of Dr. H. R. O'Brien and Dr. J. V. Anderson, a third group of cases from Cattaraugus County was studied in December, 1939, and January, 1940. It consisted of seven children in one family, two of them with paralytic anterior poliomyelitis, one recovered from a febrile illness without paralysis, and the other four not clinically affected; and two other individuals, one with residual paralysis six weeks after the onset and another with no paralysis one month following illness. The specimens from this group were obtained from three to six weeks after onset of the disease. They were treated by prolonged shaking with ether, and while no monkeys contracted clinical poliomyelitis, two died of peritonitis and paralytic ileus. No microorganisms could be cultured from either the peritoneum or heart's blood.

During August and September, 1939, a number of stool specimens were received in the laboratory from Buffalo, N. Y., and stored at an average temperature of -5° C. until they could be studied. On January 31, 1940, one of these specimens from an infant ill with paralytic poliomyelitis, received September 9, 1939, was selected and treated by the original method of shaking very briefly with ether. Cultures from the treated suspensions showed no growth. A monkey was inoculated and developed severe anterior poliomyelitis. The virus has been given three subsequent passages. It is of great interest that the virus remained virulent in this stool, frozen in the refrigerator for 124 days, or throughout the winter months.

Note.—In patients A. Mc. and S. C. the material for final second passage was pooled as indicated, both for fear of losing the strain and to conserve monkeys. It was desired to establish a typical second passage only.

More complete clinical data on four of these cases are discussed by Dr. A. C. Silverman (Am. J. Pub. Health 21: 593, 1941).

Because passage monkeys sometimes fell ill with an acute disease showing involvement of the central nervous system but without flaccid paralysis, no stools were considered to have unequivocally contained the virus of anterior poliomyelitis until at least one typical second or further passage was obtained (see Table I). Thus, even though a monkey showed fever after from five to ten days, accompanied by tremor and other clinical signs of encephalitis, and even though such animals on autopsy showed meningitis with mononuclear cell exudate, perivascular accumulations and nerve cell destruction with neuro-

phagia in the brain stem or cortex but not in spinal cord, the evidence was considered insufficient. Further passages were made until a monkey developed, clinically and histopathologically, typical anterior poliomyelitis. As other authors^{3, 4} have given detailed protocols of the disease in monkeys, it seems superfluous to do so here. Characteristic lesions consisted of neurone necrosis with neuronophagia in the anterior horns and usually elsewhere; perivascular cell accumulations usually of mononuclear cells, but occasionally with polymorphonuclear cells predominating; some degree of leptomeningitis, often of scattered distribution; occasionally small perivascular hemorrhages in the nervous tissue or meninges; signs of microglial activity and elastotodendrosis of astrocytes about local lesions, and various degrees of Nissl's degeneration in ganglion cells. Lesions were observed in all major divisions of the spinal cord, the medulla, pons, mesencephalon, diencephalon, roof nuclei of the cerebellum, and the motor cortex, as well as in dorsal root ganglia and Gasserian ganglia. No lesions were seen in the thoracolumbar autonomic ganglia.

In many monkeys focal interstitial nephritis was observed. Similar lesions, however, have since been found in a monkey dying of unknown cause, and in two monkeys dying of bacillary dysentery.

All intracranial inoculations in monkeys (*Macacus rhesus*) were made into the left frontal lobe. All monkeys were sacrificed by light ether anesthesia and intracardiac air embolism. None were permitted to die spontaneously. Autopsy in each case was performed as soon as death supervened. In addition to the parts of the nervous system mentioned sections were taken routinely from all visceral organs, including the major divisions of the gastrointestinal tract, and from the peritoneal lymphatics. The viscera were fixed in Zenker-acetic solution and stained with hematoxylin and phloxine. Central nervous system tissue was fixed in Zenker-acetic solution, formalin, ammonium bromide, and 70 per cent alcohol. Hematoxylin-phloxine and thionine stains and silver carbonate and gold-chloride sublimate impregnations were done in each case, and when it seemed indicated, scarlet red stain (for demonstration of fat) was made. In only one instance, however, was any considerable fatty change observed.

All autopsies were controlled by cultures and film preparations from the peritoneum, brain, and heart's blood on horse blood agar. In no case were any significant bacterial findings observed. All passage suspensions were controlled by culturing on horse blood agar, with no significant bacterial findings. All inoculations into monkeys were controlled by parallel inoculations into young Swiss mice. The mice were observed for one month. No instances of disease were noted. Virus strains, if one may use the term in this connection, from three different cases were put intracranially and intraperitoneally into Eastern cotton rats (*Signodon hispidus hispidus*), but no successful passage was obtained.

Serial "faith" passages through six passage generations of cotton rats yielded no results. Cotton rats and young Swiss mice intoxicated with guanidine hydrochloride, diorthocresylphosphate, cadaverine hydrochloride, and ethylenediamine dihydrochloride, all failed to contract the disease. All were observed for a month following intracranial and intraperitoneal inoculation with tissue

containing virus. All chemical intoxications were maintained over a period of from ten days to two weeks, starting usually five days previous to exhibition of the virus. Three rats put on thyroxine injections all died during manipulation for taking temperatures before poliomyelitis would have been expected to develop.

It is worth noting here that many of our cotton rats died suddenly during or after very brief handling. We were unable to find a cause for death on autopsy, though it may be significant that immediately post mortem there was marked peristaltic activity observable through the intact abdominal wall.

SUMMARY AND CONCLUSIONS

Single random specimens of stool were obtained from a total of 17 cases of typical, abortive, or atypical suspected anterior poliomyelitis and inoculated into monkeys, with five "takes." Nine of these cases had clinical paralysis. Two were clinically abortive types. Two were atypical. Four were contacts without clinical signs or symptoms.

Eight stool specimens were treated by the method outlined, with shaking from five to ten minutes with ether. Of these eight cases, seven had paralysis. From five of the paralyzed cases, successful transfers of the disease into monkeys were obtained.

Nine stool specimens were treated by the method outlined, but the suspensions were shaken for two to four hours with ether. Of these nine cases, two were paralytic; none of the inoculated monkeys showed signs of poliomyelitis.

One of the infective stool specimens was collected as late as forty days after the probable onset of the disease.

One of the stool specimens kept at a temperature of -5° C. remained infective for 124 days after collection.

All stool and monkey cord passages were controlled by mouse inoculation.

All successful passages were from the stools of infants under two years of age, in four cases at least, on similar diets.

It does not appear to me that any deductive conclusions may be drawn with certainty at this stage of the investigations. However, the question under what conditions poliomyelitis virus will remain infective in stools seems to be of interest.

BEHAVIOR OF THE RECIPIENT'S LEUCOCYTE COUNT FOLLOWING TRANSFUSION OF PRESERVED BLOOD*

J. ANDREW GRAHAM, M.D., AND WILLIS M. FOWLER, M.D., IOWA CITY, IOWA

THE increasing use of preserved blood for transfusions has raised many questions regarding its effectiveness as compared to that of fresh blood. Among these questions is its relative value in agranulocytosis and in septicemia or other infectious conditions, both as regards the transferal of immune bodies and the leucocytes themselves. Although there is still a difference of opinion as to the effectiveness of any transfusion in combating an infection, the procedure is frequently used.

It has been shown that with a transfusion of fresh blood the transfused leucocytes disappear from the recipient's blood stream within two and one-half hours and that such a transfusion does not cause a significant increase in the leucocyte count.¹ Since the life of a normal leucocyte is from one to five days, and the number of these cells in the ordinary transfusion is relatively small, one could not expect a significant increase in the recipient's count. With preserved blood it has been shown that there is a gradual disintegration and reduction in the number of leucocytes during the period of storage, and it has been recommended that this blood not be used in patients with agranulocytosis.² The value of transfusions of preserved blood in infectious states has also been questioned, since the degenerative changes in the neutrophils reduce their phagocytic activities.³ On the other hand, it has been suggested that the products of disintegration may stimulate the formation of new cells in the recipient.²

In order to determine the effect of transfusion of preserved blood on the recipient's circulating leucocytes, counts were made before and after the giving of blood from the "blood bank." The age of the blood varied from one to twenty-five days, as is noted in the tables, and the preservatives used were either sodium citrate or a dextrose-citrate mixture, as described by DeGowin.⁴ The patients selected for study were those without an acute infection or recent hemorrhage. No patient was studied during a postoperative period. In one group of 15 patients leucocyte counts were done at two-hour intervals following transfusion, and in a second group of 12 patients counts were done at twenty-four-hour intervals, so that information might be obtained on either an immediate or a delayed rise due to stimulation from the disintegration products. The results are shown in Tables I and II.

13	2,000		1,650	2,100			23	Aplastic anemia
14	11,300		11,500	10,800			19	Ulcerative colitis
15	10,050		10,650	10,800			2	Carcinoma of stomach

TABLE II
LEUCOCYTE COUNTS AT TWENTY-FOUR-HOUR INTERVALS

CASE	INITIAL COUNT		24 HOURS	48 HOURS	72 HOURS	96 HOURS	120 HOURS	AGE OF BLOOD DAYS	DIAGNOSIS
1	8,500	Transfusion	9,600	9,400	10,100	11,200	9,000	1	Pernicious anemia
2	6,900		7,200	8,200	6,350	6,900	7,500	6	Peptic ulcer
3	7,200		7,000	7,800	6,350	7,750	6,250	6	Carcinoma of cervix
4	6,300		7,050	8,100	7,400	7,000	7,650	22	Carcinoma of cervix
5	10,200		10,550	9,350	8,050	8,400		3	Nutritional anemia
6	12,350		8,900	9,450	8,800	8,200		16	Carcinoma of stomach
7	5,250		5,850	4,250	3,600	3,700		25	Carcinoma of colon
8	3,600		3,800	3,400	3,900	3,700		2	Leucemic leucemia
9	3,350		3,750	3,300	2,950	3,650		4	Aplastic anemia
10	11,300		9,650	10,050	10,350	10,050		19	Ulcerative colitis
11	8,450		9,450	8,660	7,900			10	Hypochromic anemia
12	8,300		7,600	7,000	7,900			25	Incomplete abortion

Examination of these tables reveals that there was no consistent change in the leucocyte count as a result of the transfusion. An elevation in the count occurred in some cases, but this was not constant; in other cases a reduction in the count was noted. These variations are no greater than can be accounted for by the unavoidable error in the method, the diurnal variations, or the rhythmic variations in the circulating leucocytes.⁵⁻⁷ The results are in accord with what one would expect from our knowledge of the life of the leucocytes and their behavior during storage. The age of the blood made no difference in the results nor did the type of case to which it was given. In aplastic anemia one could expect no latent rise from the stimulation of disintegration products, and although such a reaction might occur in cases with normal bone marrow, it was not encountered in this group of cases.

Transfusions of preserved human blood produce no constant or significant changes in the leucocyte count of the recipient.

THE EFFECTS OF DECREASED TEMPERATURE ON THE ACTIVITY OF INTACT MUSCLE*

W. W. TUTTLE, PH.D., IOWA CITY, IOWA

SINCE muscular contraction involves intrinsic chemical and physical changes, the influence which a fall in temperature has on muscular activity may be anticipated by studying the effects which temperature changes have on the processes involved in muscular contraction. However, a mere statement of the qualitative effects which temperature changes have on muscular contraction is inadequate for a complete explanation of poor performance, and also muscle injury, experienced by individuals who are called on to exercise strenuously.

In order to have a clearer picture of the effects of lowering the temperature of a muscle on its activity, the experiment herein reported was performed. To make the experimental data parallel the conditions as they actually exist, the activity of the intact gastrocnemius muscle and its antagonist when exposed to cold, was studied. In order to determine the effects of lowering the temperature of the muscle on its activity, the form curve of a normal muscle was compared with that of the same muscle after it has been cooled for various periods of time.

The gastrocnemius muscle was caused to contract by applying submaximal break induction shocks to it. This was accomplished by attaching one pole of the inductorium to an electrode placed over the medial motor point of the muscle, and the other pole to an electrode placed on the thigh, over an indifferent area. A foot switch was employed in the primary circuit so that the experimenter's hands were free to manipulate the recording apparatus.

The subjects were placed in a prone position on a table with the feet well over the edge. A cord was attached to the toe of the subject's shoe, thence over a pulley under the table to a recording stylus suspended from a rubber band. The rubber band furnished the means by which uniform tension was maintained on the muscle throughout the experiment. A signal magnet, placed in the primary circuit, was superposed above the recording stylus. A 100 double vibration electrically driven tuning fork was placed between the recording stylus and the signal magnet. The record was made on an extension kymograph which

*From the Department of Physiology, University of Iowa, Iowa City.
Received for publication, August 1, 1940.

was operated manually. Obviously, the records were recorded upside down, since a contraction of the muscle caused an extension of the foot, thus pulling the recording stylus down.

The procedure in securing the data was first, to make control records from the muscle, and then pack the leg in ice. After five, ten, and twenty minutes of cooling, additional records were made. Fifteen to twenty tracings were secured under each condition studied.

By means of ordinates the response of the muscle was divided into its latent period, periods of contraction and relaxation. The length of each period was determined by counting the number of tuning fork vibrations between the ordinates.

THE DATA

Data were collected from 12 individuals. The values given in Table I are the means of no less than 15 responses per period for each individual.

TABLE I

A COMPARISON OF THE EFFECT OF COOLING ON THE PERIODS OF RESPONSE OF THE INTACT GASTROCNEMIUS MUSCLE

	LATENT TIME	PER CENT INCREASE	CONTRACTION TIME	PER CENT INCREASE	RELAXATION TIME	PER CENT INCREASE
Normal	0.024 ± 0.002		0.089 ± 0.006		0.267 ± 0.034	
Cooling 5 min.	0.027 ± 0.002	12.5	0.108 ± 0.012	21	0.432 ± 0.035	62
Cooling 10 min.	0.030 ± 0.002	25	0.130 ± 0.015	46	0.574 ± 0.045	115
Cooling 20 min.	0.033 ± 0.002	37.5	0.162 ± 0.024	82	0.726 ± 0.061	172

Although the well-known facts relative to the effects of cooling muscle are demonstrated by the experiment, the phase of activity in which we are most concerned in this investigation is the period of relaxation. After five minutes of cooling the relaxation time is increased 62 per cent, while the period of contraction and the latent time are increased 21 per cent and 12.5 per cent, respectively. This means that relaxation is affected three times as much as contraction and five times as much as the latency of the muscle. Ten minutes of cooling increases the period of relaxation 115 per cent, while the contraction time is increased only 46 per cent and the latency 24 per cent. Under this condition, relaxation is increased 2.5 times as much as contraction and 4.6 times that of the latency. After twenty minutes of cooling the situation is similar. Relaxation is increased 172 per cent, contraction 82 per cent, and latency 37.5 per cent. Under this condition, relaxation is increased 2.1 times as much as contraction and 4.6 times as much as latency. In view of these facts one is justified in emphasizing that cooling a muscle not only affects the relaxation more than any other period of its activity, but also slows this period from two to three times as much as the contraction.

The effect of cooling on muscular relaxation is especially important to athletes who participate in sports, such as sprinting, during which the muscles perform explosive movements. As far as the latent and contraction periods are concerned, the warming-up of a muscle may be adequate, but from the point of view of relaxation at that stage it is totally unprepared for explosive action. Such a condition makes for poor performance, since a succeeding contraction cannot occur until the muscle relaxes from the preceding contraction.

A complete warm-up also is important from the standpoint of muscle injury, since when the driving muscles contract, their antagonists must relax in a synergistic fashion. Injury to an improperly warmed-up antagonist is not uncommon. Such injuries can only be prevented by sufficient preliminary exercises to reduce the relaxation time of an antagonist commensurate with the reduction in contraction time.

It is also worthy of note that muscle injury may occur if a properly warmed-up muscle is exposed to a cold environment. Such occurrences as these can be prevented only by protection from cold. In fact, many sprinters, running from a protected environment into a cold draft or breeze, have been observed to have experienced muscle injury.

SUMMARY AND CONCLUSIONS

An investigation of the effect of cooling intact muscle shows that the lowering of the temperature increases the relaxation time two to three times as much as the contraction time of the muscle. Inadequate relaxation due to an improper warm-up is sufficient to explain poor performance in explosive bouts of exercise such as sprinting. Also, injury to muscles antagonistic to driving muscles is explained on the basis of a prolonged relaxation time, due to either an inadequate warm-up, a cold environment, or a sudden change in the environment.

A STUDY OF THE THERAPEUTIC EFFECT OF SULFAPYRIDINE IN PNEUMOCOCCUS INFECTED MICE IN ATMOSPHERES OF VARYING OXYGEN TENSION*

ALVAN L. BARACH, M.D., AND NORMAN MOLOMUT, Ph.D.
NEW YORK, N. Y.

INTRODUCTION

INVESTIGATIONS on the mechanism of the action of sulfanilamide and its derivatives *in vitro* have led to the theory that an oxidation product of the drug is responsible for the bacteriostasis noted (Mayer;¹ Ottenberg and Fox;² Fox, Cline, and Ottenberg³). As a corollary to this theory the bacteriostatic action of the drug should be lessened under anaerobic conditions of culture. Swift, Lancefield, and Goodner⁴ found that with 6 strains of hemolytic streptococci, if removal of oxygen and reduction are complete before inoculation of the media with the organisms, bacteriostasis by sulfanilamide is prevented. Shinn, Main, and Mellon⁵ demonstrated that reduction of the oxygen in superambient air of broth cultures of type I pneumococcus reduced or prevented bacteriostasis by sulfanilamide. This inhibition of bacteriostasis was also noted under complete anaerobic conditions. When, however, the superambient air contained 0.04 per cent oxygen, this inhibition effect was absent. Fox,⁶ studying

this same phenomenon, concludes that complete initial deprivation of oxygen interferes with bacteriostasis and increased oxygen availability magnifies bacteriostasis. Unpublished studies by Fox⁷ on the effect of oxygen deprivation on the action of sulfapyridine on pneumococci demonstrate that the action of the drug is lessened under anaerobiosis. This is in disagreement with Long,⁸ who could not demonstrate this effect. Long's report shows that in both aerobic and anaerobic cultures he obtained sterility. Using streptococcus as the test organism, Long finds a lessened bacteriostatic action of the drug under anaerobic conditions.

On the basis of this work it was felt that perhaps a reduction of the oxygen saturation in the blood of mice would similarly interfere with the action of sulfapyridine on pneumococcus septicemia. Conversely, an increase in oxygen saturation should enhance the bacteriostasis.

60	17	Infected and drug	1	1	2	3	5	1	2	1		17	0

METHODS

For these experiments we used a mucoid type I pneumococci which was passed through rabbits once a month and kept in rabbit's blood under vaseline seal. For infection a subculture was made using 0.5 c.c. of this stock culture. The infecting volume was 0.3 c.c. of the given dilution (in broth) of a five-hour subculture, injected intraperitoneally.

The drug sulfapyridine was suspended in 10 per cent gum acacia and fed twice daily, giving 30 mg. of the drug per day for six days and 15 mg. daily for the seventh and eighth days. The given atmospheres were continued for twenty-four hours after the last drug dose, and the experiment was considered complete twenty-four hours after discontinuation of the gases. In all cases, cultures from heart blood were taken at autopsy and the organisms were recovered. In each of the experiments a group of normal mice was put in with the low oxygen group to control deaths due possibly to the low oxygen.

To control the factor of the effect of varying the oxygen atmosphere on pneumococcus septicemia, three groups of 15 mice each were infected with 100 M.L.D. of the culture and subjected to 8 per cent oxygen, 60 per cent oxygen, and room air (20.8 per cent), respectively. In all groups the mice died between fourteen and twenty-four hours. The distribution of deaths was approximately the same in all three groups.

Varying the oxygen concentration of the atmosphere did not appear to affect the mortality rate.

Five additional similar experiments were run in which a total of 225 mice were exposed to low and high oxygen percentages, and the conditions in Experiments 1 and 2 duplicated. Since the results in these experiments were confirmatory of the foregoing data, a detailed presentation is not given.

CONCLUSIONS

In cultures of pneumococci anaerobic conditions have been reported to prevent the bacteriostatic action of sulfapyridine.

Pneumococcus-infected mice were treated with sulfapyridine in atmospheres of low oxygen tension (8 per cent), air and high oxygen tension (60 per cent) without significant effect on the mortality rate. Varying the oxygen tension of the atmosphere does not appear to modify the effectiveness of sulfapyridine in pneumococcus septicemia.

It is acknowledged that these results do not apply to pneumonia in which the oxygen tension of the capillary blood may fall to far lower levels.

GOLD COLLOID AND COLLOIDS OF OTHER HEAVY METALS IN THE TREATMENT OF RHEUMATOID ARTHRITIS*

JAMES M. TARSY, M.D., BROOKLYN, N. Y.

THE rapidly accumulating literature on the use of gold salts in rheumatoid arthritis is in apparent harmony on the following two points: (1) Gold in the form of its salts is perhaps the most efficient agent known in the treatment of rheumatoid arthritis. (2) The toxic or untoward reactions so frequently encountered are a serious drawback to the use of this drug. The clinical results¹ obtained with gold sodium thiomalate in a recent investigation undertaken with the purpose in view of reducing the frequency and severity of toxic phenomena served to strengthen these views.

With the two enumerated points in mind, therefore, I was induced to search for some similar or related agent, or agents, that might incorporate all the beneficial therapeutic qualities of gold salts without their serious toxic effects. It was also my aim to ascertain whether the beneficial attributes of gold were due to something inherent in the gold radical alone, regardless of chemical affinity, or whether these attributes were likewise demonstrable in the radicals of other heavy metals such as platinum, bismuth, etc.

Therapeutic research on the use of gold for some unascertained reason appears to have been limited to the salt. Review of the literature failed to discover any published reports on the treatment of rheumatoid arthritis with the colloid of gold or of other heavy metals. Several authors have reported using "colloidal" gold, but on closer investigation it was found that the term "colloid" had been used somewhat indiscriminately.

As is well known, the inorganic salts of gold are very reactive chemically. Most of them decompose readily, with the liberation of metallic gold, while even those which are generally regarded as fairly stable are quite reactive. As an example, a dilute solution of gold chloride, AuCl_3 , decomposes on heating, while on exposure to direct sunlight metallic gold is precipitated and hydrogen peroxide is formed in the solution. The chemical reactivity of the somewhat more stable aurichloric acid, HAuCl_4 , was observed by Boyle in 1663, who found that it would color the skin, nails, or ivory a purplish-red tint when exposed to light. This, of course, immediately calls to mind the staining of the skin experienced with solutions of silver nitrate. Even gold sodium thiosulfate, which has achieved a definite measure of recognition in the treatment of lupus erythematosus, is unstable, its solutions becoming yellow and decomposing on standing.

*From the Arthritis Clinic, St. Mary's Hospital, Brooklyn, William McCollom, M.D., attending physician.
Received for publication, August 13, 1940.
The colloid solutions for this study were especially prepared by Crookes Laboratories, Inc., New York, N. Y.

It seems obvious, therefore, that in gold we have a highly reactive element, and that this reactivity may in part be responsible for the considerable toxicity of its salts. The thiomalate with which my associates and I have had considerable experience is an organic salt of gold which does not seem to be quite so reactive as the thiosulfate, and which in consequence can be, and is, used in considerably larger doses. However, even the thiomalate must be administered with considerable caution.

In view of this toxicity it seemed desirable to explore the possibility of introducing gold in a form which was less reactive chemically and which, in consequence, might permit a more sustained, effective, and less toxic form of therapy. Colloidal gold appeared to offer definite possibilities.

Within recent times reports on the use of dilute solutions of colloidal gold in the treatment of malignancy have been published,²⁻⁸ and although the results obtained have in no way been conclusive, there are indications that even in the dilute solutions employed colloidal gold exerts a definite analgesic action.

Although metallic gold itself is a very stable metal, being unaffected by air and water and many ordinary laboratory reagents and solvents, it is not absolutely insoluble. When exhibited as a colloid, this element consists of innumerable particles of metallic gold. It seemed, therefore, particularly in this extremely subdivided form, that when injected in the body it would act in a manner similar to that ascribed to colloidal silver.

It will be remembered that when colloidal silver was made available commercially, new therapeutic fields were created for this element, which, in the form of its soluble salts, was far too reactive and toxic for use in more than very dilute solutions, except where a definitely caustic action was desired.

New and Nonofficial Remedies, referring to colloidal silver preparations, points out that the silver in these colloidal suspensions does not exist to any great extent in the free ionic state, and, therefore, does not precipitate chlorides and proteins. As a result it is noncorrosive and nonirritant, yet retains a definite degree of antiseptic action. This silver action is not proportionate to the total silver content of the colloidal silver preparation and varies with the different colloidal silver compounds. The antiseptic action of these colloids is undoubtedly due to the liberation of continuous, very low concentrations of silver ions.

Weiser⁸ states that the more finely subdivided the silver, the stronger its bactericidal action. By analogy, therefore, colloidal gold, because it is almost devoid of gold ions and consequently reduced of its chemical reactivity, should not react immediately with the albumen, proteins, and salts which are found in the body, thereby permitting intramuscular administration without any immediate local irritation or general reaction.

My experience indicates this to be true. Furthermore, the billions of tiny particles of metallic gold should conceivably act as depots for the formation of gold ions, to which part of the action of gold salts may be ascribed, resulting in a more sustained action of the colloid but of a somewhat lower intensity than that obtained with gold salts.

There is another factor which might, theoretically, impart to a colloid of gold a beneficial action probably not associated with gold salts. It is well

known, for instance, that the injection of any colloid into the blood stream is attended by a certain amount of shock similar to that which usually follows the injection of a nonspecific protein. Thus, when using colloidal gold, with the therapeutic action of the gold itself, one is able to combine a mild nonspecific reaction.

Colloidal platinum (at.wt. 195.2) and colloidal bismuth (at.wt. 209.0) were included with gold in this study, since these metals have atomic weights approximating that of gold (197.2), and since it was thought possible that some common heavy metal action might be demonstrable therapeutically. Selenium, though not a heavy metal, because of its vaunted analgesic action in malignancies, which seemed to correspond in some way with this action of colloidal gold, was also included in this study. Selenium, however, together with platinum and bismuth, gave insufficient promise of therapeutic usefulness and was discontinued early in the study. Lead and some of the other metals in the higher scale of atomic weights were discarded as probably being too toxic.

It was felt that at least a period of two years from the initiation of this work should elapse before a more or less accurate evaluation of the therapeutic efficacy of the agents employed could be attempted with any degree of accuracy.

The duration of treatment in each individual case varied from three to twelve months. As with the salt, treatment consisted of three series of injections. Each series comprised 1 Gm. of metallic gold, an interval of six weeks being interposed between each series. An average of approximately 1 Gm. of gold was administered in each individual case.

In the beginning of this work a 0.1 per cent solution of colloidal gold was injected in 5 c.c. doses intragluteally. With this relatively dilute solution the actual amount of gold administered was very small, amounting to no more than 5 mg. (0.005). In spite of the relatively large quantity of solution injected, however, it was felt that larger doses of metallic gold, equal to those used by other investigators and myself, should be employed if an actual comparison of therapeutic results was to be obtained. Therefore, a second and more concentrated 1 per cent solution was prepared in which 2.5 c.c. of the suspension corresponded to 0.025 Gm. of metallic gold. This more concentrated solution in a number of cases resulted in an unsightly coppery discoloration at the point of injection, and for this reason had to be administered intragluteally. In both these suspensions the gold was "stabilized" with an emulsoid colloid containing 0.3 per cent trieresol.

For the sake of this therapeutic comparison it was deemed unfortunate that larger amounts of gold corresponding to the higher dosage brackets (0.05 to 0.1 Gm.) employed by Forestier and other investigators were not used at this time. In justification it must be remembered that in this study of the therapeutic effects of colloidal gold in rheumatoid arthritis we were treading, more or less, on virgin soil, and for that reason, had to exert a greater amount of caution. In passing, it must be mentioned, however, that far larger doses than those here employed have been used in the treatment of carcinoma and other malignancies.

Results of Colloidal Gold Therapy in Rheumatoid Arthritis

Total No. Cases Treated	Unimproved	Slight	Moderate	Marked	Uncertain
36	9	4	2	19	2

Fifty patients were injected with the above-mentioned colloids. Of these, 36* received gold, 4 platinum, 4 bismuth, and 6 selenium. Practically all these patients had received some previous form of therapy with unsatisfactory results. Two had been treated with gold salts in the form of gold sodium thiomalate intramuscularly, and two had had gold sodium thiosulfate with equally disappointing results. Among the series treated with the gold colloid were included two cases of generalized fibrositis that for years had failed to respond to any other form of therapy. The duration of the disease varied from three months to fifteen years. As to the severity or the grade of involvement of the rheumatic process, it might be said that the patients conformed to the average run of chronic cases currently seen in a large metropolitan clinic. The pathology varied from marked deformities as found in patients bedridden for a number of years, to those milder forms merely showing periarticular soft tissue changes. The usual laboratory procedures essential to the use of gold salts, i.e., sedimentation rate, complete blood studies, and urinalysis, were carried out before, during, and after initiation of therapy. Of 36 patients treated with gold colloid, 19, or 52.7 per cent, showed a definite improvement, while 9, or 25 per cent, failed to show any degree of amelioration. The two patients suffering from fibrositis demonstrated a quick and gratifying response.

Statistics in over 1,600 persons treated with gold salts show that there is an average marked improvement of about 54 per cent and a total lack of improvement in approximately 13 per cent. Considering the relatively small number of cases presented in this preliminary report, the difficulty of drawing valid conclusions as to comparative therapeutic value of gold salts and the colloid of gold is apparent, and any inferences derived from this study must have, therefore, only a relative value.

DISCUSSION

Of the metallic colloids employed, gold, because of its apparent therapeutic superiority over the other afore-mentioned metals, received predominant attention.

In drawing a differential comparison between gold salts and the colloid of gold, the following three criteria appear of outstanding importance: (1) therapeutic efficiency, (2) toxicity, (3) biological action. What the results are with the use of gold salts is common knowledge and repetition appears unnecessary.

*Seven of these patients were treated in the arthritis clinics of the Brooklyn and Post Graduate Hospitals, Doctors G. E. Anderson and Edward Hartung, respectively, in charge.

(1) *Therapeutic Efficiency of Colloidal Gold*.—In keeping with a definite subjective improvement in the majority of persons treated, there was a tendency toward regression of those signs which together comprise the rheumatoid picture. As in the case of gold salts, this regression consisted of reduced pain and peri-articular swelling as well as of increased function of the parts involved. It was my impression, however, that the therapeutic response was lacking the quick, dramatic character often observed with gold salts.

(2) *Toxicity*.—In contrast to the highly toxic nature of gold salts, as occasioned by their ready solubility and intimate chemical action on the body tissues, thereby detracting from their value as routine therapeutic agents, the colloid, in the individual and total doses already mentioned, gave little evidence of such toxicity. This almost complete lack of toxicity is in conformity with the physico-chemical structure of all colloids, which, as has already been mentioned, are, chemically, relatively inert substances and therefore exert little, if any, destructive action on the body tissues. With the colloid, for instance, there were none of those toxic, and sometimes alarming, clinical manifestations so frequently obtained with gold salts. In the entire series treated, one patient developed an enlargement of the axillary lymph glands. This patient, upon investigation, had been previously treated with gold salts. This glandular reaction has been found to be not an uncommon sequel to the use of the salt as well.

(3) *Biological Action*.—Biological action as determined by the sedimentation rate, complete blood studies, and urinalysis are as follows: As with gold salts, there was a parallelism between the drop in sedimentation rate and clinical improvement. This drop, however, in keeping with the slower therapeutic response, was definitely delayed.

At no time did any marked or abnormal changes occur in the urinary picture. If one realizes that a good part of any heavy metal, such as gold or mercury, is eliminated through the kidneys, one is again struck with the basically inert nature of the metallic colloids.

The essentially different nature of gold salts as compared with colloidal gold has been further emphasized by bacteriostatic tests with the sera of patients treated with both these substances. For instance, the sera of patients treated with gold salts showed a very active bacteriostatic power even after as few as three injections. In contrast, the colloid-treated serum utterly failed to retard the growth of organisms. These experiments conducted independently by Hartung and Sabin were in complete accord on the results obtained. This, in my opinion, is not necessarily proof of the inefficacy of the colloid. The very nature of its action, i.e., slower ionization, greatly diminished chemical reactivity, etc., would eliminate any attributes of great bacteriostatic power, especially after merely three or four injections.

MECHANISM OF COLLOID THERAPY IN RHEUMATOID ARTHRITIS

Studies of the reticulo-endothelial system in the deposition of colloidal and particulate matter in articular cavities furnish us with some very interesting data. Kuhns and Weatherford¹⁰ describe experiments dealing with the deposition of trypan blue in the reticulo-endothelial system in and about the joints of the albino rats. These authors concluded that the colloidal and particulate matter used in their experiments is carried by the blood stream from various

parts of the body and stored in the histiocytes of the synovial membrane. Some amounts are also stored in the bone marrow, intermuscular septi and articular fat pads. Inflammation of the articular tissues tends to increase the amount of particulate matter deposited. The inferences which follow these experiments are that stimulation of the reticulo-endothelial system might be effected by the deposition of colloidal matter and that this stimulation should prove a definite advance in the treatment of articular diseases.

It is my belief that by the use of colloidal gold we are employing a substance which, as in the case of trypan blue, is deposited in various parts of the body, particularly the reticulo-endothelial system. The deposition of finely divided particles of gold in the histiocytes of the synovial membrane should result in the removal of products of inflammation, increase the defense mechanism in the synovial membrane, and likewise produce a stimulation of the general reticulo-endothelial system.¹¹

CONCLUSION

The conclusions derived from a review of the results obtained with gold salts and with the colloid of gold are as follows: Gold salts are more active therapeutically and likewise are more toxic. In view of the known clinical and biological action manifested by gold salts in the more severe forms of rheumatoid arthritis, they are probably superior to the colloid. On the other hand, the encouraging and apparently superior results obtained with the colloid, as compared with some of the older agents, especially in the less severe forms of rheumatoid arthritis and in fibrositis, are in support of the opinion that a therapeutic niche lying somewhere between the salt and some of these older and less spectacular agents should be conceded the colloid.

These results, of course, are not incontrovertible, but in view of the encouraging results obtained thus far by this study, and in view of the scarcity of actually desirable therapeutic agents in rheumatoid arthritis and other forms of infectious arthritis, colloid gold therapy should be given the opportunity of continued unbiased investigation. It might also appear that this form of therapy might be especially desirable in the treatment of generalized fibrositis with an infectious background, in the arthritides of known infectious origin, or in the incipient forms of rheumatoid arthritis.

SUMMARY

1. In view of the toxicity of gold salts in the treatment of rheumatoid arthritis which renders this type of therapy a definitely hazardous one, the therapeutic possibilities of some of the less soluble forms of gold were investigated. Gold in colloid form was chosen because of certain definite chemical considerations.

2. With the purpose in view of determining whether the beneficial attributes of gold were (something) inherent in the gold radical alone or whether these attributes were also demonstrable in the radicals of other heavy metals, platinum and bismuth were also employed.

3. Selenium, though not a heavy metal, because of its vaunted analgesic action in malignancies, was likewise used.

4. Platinum, bismuth, and selenium gave insufficient promise of therapeutic usefulness early in this clinical study and were, therefore, discarded.

5. Thirty-six patients in all were treated with the gold colloid over a period of two years. The colloid was given intramuscularly in individual and total doses equal to those I employed in a previous study with gold salts.

6. As a result of the present findings it is my opinion that in the gold colloid we are dealing with a more or less chemically inert form of gold, which, in contrast to gold salts, is only slightly soluble when injected in the body, and hence far less toxic.

7. The therapeutic results obtained with gold colloid may be partially explained on the basis of distribution of innumerable metallic particles throughout the reticulo-endothelial system, particularly in the deposition of these particles in the histiocytes of the synovial membrane, with the gradual liberation of gold ions and their consequent action on the body tissues.

8. No dramatic therapeutic qualities are espoused for colloidal gold in rheumatoid arthritis. In view of the beneficial response obtained in the present series, and because of the marked decrease in toxicity, it appears, however, that gold in colloid form is an agent worthy of further study and consideration for treatment of rheumatoid arthritis and generalized fibrositis with a toxic or infectious background.

I am indebted to E. A. H. King of the Crookes Laboratories, Inc., for his technical advice in preparing this paper.

THE RELATION OF THE NASOPHARYNX TO ULCERATIVE COLITIS*

PRELIMINARY REPORT

SAMUEL WEISS, M.D., F.A.C.P., ALEXANDER SLANGER, M.D., AND
SANFORD GOODFRIEND, M.D., NEW YORK, N. Y.

A VOLUMINOUS literature has developed in the field of ulcerative colitis as to etiology and treatment. It is with full knowledge of these facts that we add our preliminary report of treatment of this condition.

Nonspecific ulcerative colitis is a chronic disease of unknown etiology, characterized by exacerbations and remissions, with symptomatology of bloody diarrhea and loss of weight, with proctoscopic findings of an edematous, granular, easily bleeding mucosa with ulcerations, either punctate or serpiginous; with blood findings of a secondary anemia, x-ray findings of the colon showing loss of haustrations and narrowing of the lumen. In these cases bacteriologic studies do not reveal any *amoeba histolytica*, *B. dysenteriae*, or diplostreptococci.

Our studies began four years ago when it became apparent to one of us (S.W.) as well as to others, notably Kunstler, Bargen, and Darrow, that exacerbations in ulcerative colitis were preceded very frequently by upper respiratory infections. We then began to study cultures taken from the nose, throat, and rectosigmoid mucosa of ulcerative colitis cases, and collected a series of 15 cases between 1934 and 1938.

The ages of these patients varied from 13 to 45 years, with typical histories of from five weeks' to eleven years' duration. Most of these patients had been under medical care before coming under our observation. The symptomatology included abdominal cramps, bloody diarrhea, loss of weight, weakness, and anemia. The proctoscopic findings showed granular mucosa, freely bleeding and ulcerated. Bacteriologic studies of the nose and throat revealed *staphylococcus albus*, 6 cases; hemolytic streptococcus, 4 cases; streptococci (nonhemolytic), 2 cases; *Streptococci viridans*, 1 case; *Staphylococci hemolyticus*, 1 case; *Micrococcus catarrhalis*, 1 case. Bacteriologic cultures taken directly from the mucosa of the rectosigmoid revealed *B. coli*, 9 cases; *Staphylococcus albus*, 5 cases; streptococci (nonhemolytic), 3 cases; *B. coli hemolyticus*, 2 cases; *Streptococci hemolyticus*, 1 case.

All patients except one were treated with a combined vaccine; this patient was given only a vaccine prepared from smears taken from the rectosigmoid. Vaccine from the nose and throat was added in this latter case, and after three injections of the combined vaccine, the bowel movements became formed and blood disappeared from the stools. These 15 patients have been well for a period ranging from nineteen months to four years.

*From the Department of Gastroenterology, New York Polyclinic Medical School and Hospital, Service of Dr. Samuel Weiss.

Presented before the monthly Gastroenterological Conference, May, 1939.

Received for publication, August 14, 1940.

Vaccines were prepared only from those organisms which were present simultaneously in the nose, throat, and rectosigmoid cultures. These vaccines were standardized to contain 1,000,000,000 organisms per cubic centimeter. Three dilutions were used, namely, 1:1, 1:10, and 1:100. We injected these vaccines three times a week in increasing doses from 0.1 c.c. to 1 c.c. for a total of 15 or more injections. Each week the three dilutions were used: the 1:100 the first day, the 1:10 the next injection, and the 1:1 dilution the last injection of that week. Each injection was increased by 0.1 c.c. each week.

The following is a case reported in detail because of the marked severity of the symptoms which improved after the combined vaccine therapy was instituted:

A young boy, 13 years of age, was admitted to the Polyclinie Hospital January 3, 1938, for the first time. For five weeks prior to his admission he had been having daily eight to ten loose stools, containing large amounts of bright red blood, severe generalized abdominal cramps, progressive loss of weight, and increased pallor. He also gave a history of staphylococcus infection of the eye five months previous which was treated successfully with a stock vaccine.

Physical examination revealed a pale, undernourished thin boy, weighing 108.5 pounds. Examination of the heart and lungs was negative. His nasopharynx showed no abnormality. His abdomen was markedly tender, especially in the left lower quadrant. There was no rigidity, and no masses were palpable.

Proctosigmoidoscopy performed on January 4, 1938, gave the following findings: The entire rectosigmoid mucosa showed marked redness with some false membrane formation. In places it was granular and there were numerous ulcerated areas, varying in size from a pin point to 1 cm. in diameter.

Cultures taken directly from the ulcerations showed the presence of many colonies of *B. coli* and *Staphylococcus albus*, but no streptococci. Cultures taken from the nasopharynx showed the presence of colonies of *Streptococcus viridans* and *Staphylococcus albus*. A vaccine was made of the *Staphylococcus albus*, this being the only organism present both in rectosigmoid and throat cultures.

Upon admission to the hospital the patient was given vaccine as well as other supportive therapy, such as liver extract injections, medicated enemas, and one transfusion. During the five weeks the patient remained at the hospital he failed to improve, the number of his bloody stools increased, and he had a further loss of weight, his lowest weight being 84 pounds. Following his dismissal he returned home where the vaccine therapy was continued. He also received several small transfusions at home. He began to improve about March 1, 1938, after having received 20 vaccine injections. Twelve more injections were given after this time. When seen on April 20, 1938, his weight was 104 pounds (a gain of 20 pounds in two months), and his general condition was very good. Bowel evacuations were normal.

Physical examination at this time was negative. The patient had no abdominal pain or discomfort: His hemoglobin was 68 per cent.

Proctosigmoidoscopy showed normal mucosa throughout. Cultures from the rectosigmoid mucosa showed the presence of *B. coli*, but no growth of *Staphylococcus albus*. Nose and throat cultures showed many colonies of *Streptococcus viridans* and a small number of *Staphylococcus albus*.

On September 8, 1938, his weight was 120 pounds; his hemoglobin was 78 per cent, his condition was excellent, and his bowel movements were normal.

The patient presented himself again on December 3, 1939. His health was still good. His weight was 137.5 pounds and his hemoglobin was 86 per cent. He claimed that this time he had one normally formed bowel movement daily.*

*Since presenting this paper the patient was seen several times thereafter.

COMMENT

What relation these various organisms from the nose, throat, and recto-sigmoid, as indicated in our studies, bear to the etiology of nonspecific ulcerative colitis we are not prepared to state. Whether by giving these various vaccines we are preventing upper respiratory infections, and in that way preventing exacerbations, we do not know. However, this seems to be the possible explanation of the rationale of our treatment. Nevertheless, we will continue to use this form of treatment, and hope that others will utilize it until such time as the specific etiology of nonspecific ulcerative colitis will be definitely established. We are of the opinion, as Paulson believes, that in those particular cases of ulcerative colitis, where amoeba, *B. dysenteriae*, and diplostreptococci of Barger are found, the resulting ulcerative colitis is secondary to these organisms.

CONCLUSIONS

We have discussed a series of cases of nonspecific ulcerative colitis presenting in detail one case. These cases were successfully treated with vaccines prepared from cultures from the nose, throat, and rectosigmoid containing only those organisms that were found simultaneously in the nasopharynx and rectosigmoid. We have had no recurrence in following these cases from a period of nineteen months to four years.

CLINICAL CHEMISTRY

THE EFFECTS OF INSULIN, METRAZOL, AND ELECTRIC SHOCK ON BLOOD PYRUVATE, LACTATE, AND GLUCOSE*

K. A. C. ELLIOTT, PH.D., T. D. RIVERS, M.D., F. H. ELLIOTT, PH.D., AND
B. PLATT, B.A., PHILADELPHIA, PA.

IT HAS been observed by Rivers¹ that intravenous administration of large doses of vitamin B₁ early in stupor is often effective in preventing early convulsions with patients undergoing the insulin shock treatment for schizophrenia. Demole^{1a} had noted that administration of vitamin B₁ to rabbits during twenty-four hours previous to insulin injection usually prevented convulsions. These results suggested a possible correlation between the effects of insulin and other convulsive agents and the metabolism of carbohydrate via pyruvic acid, since it is well established that vitamin B₁, or rather the vitamin pyrophosphate, is concerned in pyruvic acid breakdown. A study has, therefore, been made of the changes in blood pyruvate, lactate, and glucose, which occur during insulin shock, after small insulin injections in normal subjects, and after metrazol and electric shock convulsions.

METHODS

Insulin was administered intramuscularly; metrazol and curare were administered intravenously. The electric shock treatment consisted in the brief application of alternating current at about 120 volts through electrodes applied to the sides of the forehead by a slight modification of the procedure of Cerletti and Bini.² Vitamin B₁ was injected intravenously.†

For each set of determinations about 10 c.c. of blood were drawn from the antecubital vein, the tourniquet being removed, directly into a test tube containing 40 mg. of potassium oxalate and 0.2 c.c. of 25 per cent sodium iodoacetate using a suction apparatus. Quick mixing with iodoacetate prevented the disappearance of pyruvate which otherwise occurs very rapidly.³ The presence of iodoacetate also prevented glycolytic increases of lactic acid. As soon as possible 2 c.c. of the sample were deproteinized with tungstic acid by the Haden modification of the Folin-Wu method, and 5 c.c. were deproteinized by running into 20 c.c. of 10 per cent trichloroacetic acid. All determinations were made in duplicate.

Glucose was determined on the tungstic filtrates by the method of Benedict, using the Klett-Summerson photoelectric colorimeter. With this colorimeter it was found that the rate of color development and the time for the color to

†Vitamin B₁, thiamin chloride, was kindly supplied to T.D.R. by Eli Lilly and Company.

reach its maximum value depended upon the amount of glucose in the sample. In the usual method the solutions are cooled before adding the color reagent. Under these conditions, except with very small amounts of glucose, the color was still deepening rapidly ten minutes after adding the color reagent. Maximum color was generally reached, and readings could best be taken after fifteen to twenty-five minutes; after thirty minutes the color faded slowly.

In the presence of 0.05 per cent iodoacetate the color was found to develop more slowly; it never reached the correct value. However, if, instead of cooling the reaction mixture after the six-minute heating, the color reagent was added to the hot solution, the color developed rapidly. Under these conditions readings taken twenty minutes after adding the color reagent and diluting, gave correct values when compared with two standard solutions containing iodoacetate and run in the same manner.

Lactic acid was determined on the trichloroacetic acid filtrates, after removal of sugar with copper sulfate-copper hydroxide, by the method of Barker and Summerson.⁴ The presence of iodoacetate in the solutions to be analyzed had no effect on the results.

Pyruvic acid was determined on trichloroacetic acid filtrates by the method of Lu,⁵ as modified by Bueding and Wortis,³ the directions of the latter authors being followed exactly. Tungstic acid itself did not interfere with the determination of pure pyruvate solutions. But tungstic acid filtrates from blood could not be used for the pyruvate determinations, since low values were always obtained and, when known amounts of pyruvate were added to blood before deproteinizing with tungstic acid, the recovery was low. Evidently the protein precipitated with tungstic acid carries down some pyruvate. Complete recovery was obtained after trichloroacetic acid precipitation. The trichloroacetic filtrates could be kept for several days before analysis without appreciable change. Oxalate and iodoacetate did not interfere with the determination. While the method is more specific than the Clift and Cook⁶ determination of bisulfite-binding substances and gives much lower values with blood,⁷ it is not completely specific. It has been assumed in this paper that pyruvate itself is largely responsible for the values obtained, but it must be remembered that α -ketoglutarate and oxaloacetate, and possibly other substances, are included in the values.

RESULTS

The results of all experiments are presented diagrammatically in Figs. 1 to 17. The ordinates for lactic acid and pyruvic acid are respectively twice and twenty times the size of those for glucose.

The legends for the figures describe the material for the various experiments. All persons were initially fasting, except those represented in Figs. 16 and 17. As far as possible persons were initially resting, but the condition of the patients did not always allow this condition to be well controlled.

Lactate.—No consistent changes in the amount of lactate in the blood during insulin stupor were observed, but some fluctuations occurred which could probably be attributed to variations in muscular activity of the patients. In three of four cases of resting normal persons receiving small doses of insulin

(see Figs. 5, 7, 8), slight rises in blood lactate occurred, possibly as a result of extra visceral muscular activity due to the hypoglycemia. Rises of blood lactate in experimental animals treated with insulin have been observed and attributed to increased muscular activity by earlier workers.⁸

Metrazol and electric shock convulsions caused extremely large rises in blood lactate,⁹⁻¹¹ obviously as a result of the intense muscular contractions. The rapidity of the rise after electric shock convulsions is noteworthy. Possibly the same occurs during metrazol convulsions, but blood could not be drawn as immediately after metrazol as after electric shock. When the muscular activity was moderated by previous administration of curare, the rise in blood lactate was less marked.

Pyruvate.—Von Euler and Högborg¹² have stated that an hour after administration of 10 units of insulin to normal persons, decreases of blood pyruvate of 75 to 100 per cent were found. Though we used a similar method for pyruvate determination, we never found any appreciable decrease in blood pyruvate as a result of administration of small or large doses of insulin.

Fluctuations in blood pyruvate followed closely the direction of the fluctuations in blood lactate, and it seems clear that the amounts of these two substances are related to each other and are affected similarly by muscular activity and not specifically by insulin or the other agents. The fluctuations in pyruvate, however, were always much less wide than those of lactate. Johnson and Edwards¹³ found increases of lactate and pyruvate in blood and urine with young men after severe exercise and suggested that the pyruvate was produced, in association with lactate, by the active muscles; this suggestion was shown to be true by Bollman and Flock¹⁴ in experiments with exercising rat muscles.

It is reasonable to believe that, with large doses of insulin, consciousness is lost and other brain functions are affected as a result of a lack of oxidizable substrate (glucose) for the oxidations necessary to maintain brain activity.¹⁵ However, no correlation was observed between the state of consciousness and the level of blood pyruvate or lactate during insulin or the other treatments. Wortis and Goldfarb¹⁶ observed that injections of lactate into patients in insulin coma had little effect on the oxygen consumption of the brain and did not arouse the patient. Mann and Magath¹⁷ were unable to relieve the convulsions of hepatectomized animals with sodium lactate. With hepatectomized abdominal eviscerated rabbits, Maddock and co-workers¹⁸ found that the cortical electrical potentials could be restored by intravenous injections of glucose but not of a number of other substances including pyruvate. With patients in insulin hypoglycemia Himwich and associates¹⁹ found no significant absorption of lactic acid from the blood circulating through the brain, and Wortis and Goldfarb²⁰ found no sign of metabolism of injected lactate or pyruvate by the brain. It thus seems that lactate and pyruvate in the blood are not available for oxidations in the brain, although the brain is well known to oxidize these substances *in vitro*.

Injections of large doses of vitamin B₁ into patients in insulin stupor produced no definite effect on blood pyruvate or glucose* within the period of

*Demole²¹ found that the previous administration of the vitamin to rabbits often diminished the hypoglycemia caused by insulin.

the experiment. Platt and Lu⁷ found a lag period of several hours before the high blood pyruvate of vitamin B₁-deficient patients was affected by curative small doses (5 mg.) of the vitamin. The observation of Rivers¹ on the effect of vitamin B₁ on insulin convulsions remains unexplained by the present work. A possible explanation is that during insulin hypoglycemia slight available amounts of glucose continue to be metabolized by the brain, producing within the cells suboptimal amounts of intermediary metabolites, the oxidation of which can be sufficiently stimulated by excess vitamin B₁ to produce more normal conditions.

Bueding and Wortis³ found that the pyruvic acid content of normal blood fell in the range 0.77 to 1.16 mg. per 100 c.c., averaging 0.98. It will be noticed that our initial resting figures are mostly appreciably higher, 0.9 to 2.2, averaging 1.4. The difference may be due to the fact that Bueding and Wortis' subjects were probably more thoroughly rested than ours.

Glucose.—Short severe muscular effort is well known to raise the fasting blood sugar.²¹ Blood glucose rose rapidly and considerably in metrazol (see Meduna and Rohny;¹¹ Loman and co-workers;²² and Redlich²³) and electric shock convulsions. Exercise after small doses of insulin to normal persons also raised the blood sugar considerably (Figs. 5 and 6). During brief exhausting exercise of nonfasting normal persons, the blood sugar fell steeply and recovered during rest (Figs. 16 and 17).

SUMMARY

Neither insulin in small or large doses, nor metrazol or electric shock treatments, have any specific effect on the level of blood pyruvate, and probably none on the lactate level, in human beings. The concentration of these substances bore no relation to the blood sugar level nor to the condition of brain functions.

Blood pyruvate and lactate rose and fell together, and the rises seemed to be the result only of muscular activity. In metrazol and electric shock the rises of both substances, and of blood glucose, were very high; curare decreased the effect of metrazol convulsions on blood lactate, pyruvate, and glucose. The changes in blood pyruvate were less marked than those of lactate.

BLOOD SPECIFIC GRAVITY STUDIES*

RELATIONSHIP OF SPECIFIC GRAVITY OF WHOLE BLOOD TO SPECIFIC GRAVITY OF PLASMA, RED BLOOD CELL COUNT, HEMATOCRIT, AND HEMOGLOBIN AS INDICATORS OF HEMOCONCENTRATION*

CHARLES T. ASHWORTH, M.D., AND GEORGE ADAMS, PH.D., M.D.
DALLAS, TEXAS

THERE has been an increasing familiarity with specific gravity studies, red blood cell counts, hemoglobin determinations, and hematocrit studies as methods of measuring hemoconcentration and hemodilution in shock and related conditions. Many investigators feel that specific gravity study is the simplest and most practical method of recognizing and following hemoconcentration during the course and treatment of shock. The method of Barbour and Hamilton¹ has placed this means of study on a practical accurate basis, and Seudder² has popularized the method in the study of shock. In a previous publication,³ the specific gravity method has been demonstrated to be not only an excellent method of studying the course of hemoconcentration during experi-

*From the Department of Pathology, Baylor University College of Medicine.
Received for publication, June 9, 1941.

mental shock, but also a means of recognizing relative blood volume changes. This latter application depends upon the assumption of a relatively constant erythrocyte specific gravity. In a series of experiments on dogs in the study of shock, it was found that the erythrocyte specific gravity varied only slightly in normal animals and during the course of shock.

It has been felt necessary to investigate the erythrocyte specific gravity in human beings and to determine whether this factor is as nearly constant as it is in dogs. In this study also particular attention has been paid to the linear relationship between the various methods of indicating hemoconcentration, as well as the relative efficacy of each of these methods.

METHODS

A series of 20 normal persons with red blood cell count over 4,000,000 and a series of 10 patients, most of whom had some form of anemia, were studied to determine the specific gravity of the red blood cells. Blood was obtained by venepuncture with minimal stasis. Heparin was used as the anti-coagulant. On each sample, red blood cell counts, hemoglobin by Sanford and Sheard method¹ using a photoelectric colorimeter, hematocrit using Wintrobe tubes,⁵ and specific gravity of whole blood and plasma using the method of Barbour and Hamilton¹ were carried out. Mean cell volume, mean cell hemoglobin, and mean cell hemoglobin concentration were calculated from the red blood cell count, hemoglobin, and hematocrit. The specific gravity of the red blood cells was calculated as follows:¹

Sp. gr. of R. B. C. =

$$\frac{(\text{Sp. gr. whole blood} \times 100) - \{\text{Sp. gr. plasma} \times (100 - \text{Hematocrit})\}}{\text{Hematocrit}}$$

The efficacy of protein concentration as an indicator of hemoconcentration was studied in a series of dogs in which shock was experimentally produced during which hemoconcentration studies were carried out.

RESULTS

Table I shows the results of the studies on human beings. The specific gravity of red blood cells shows only minor variation in normal human beings, varying from 1.0936 to 1.0998, with an average of 1.0971. In patients with anemia, however, the variation was somewhat greater, from 1.0868 to 1.1045, this variation bearing slight but not absolute relationship to the mean cell hemoglobin concentration. It would appear that a close relationship between mean cell hemoglobin concentration and specific gravity of red blood cells exists, and the absence of such may be due to technical variations. It would seem that, although in anemia and other abnormal conditions, the red blood cell specific gravity may vary from the average, in the same person the factor is sufficiently constant that the specific gravity method is an accurate means of indicating relative blood volume changes. A study of the literature shows that Oestreich⁶ in 1931 studied the specific gravity of blood using methods susceptible to serious criticism; he found the specific gravity of erythrocytes around 1.09, a somewhat lower figure than that obtained here.

With the average specific gravity of human erythrocytes known, the hematocrit may be calculated from the specific gravity of whole blood and plasma as follows:

$$\text{Hematocrit} = \frac{(\text{Sp. gr. whole blood} \times 100) - [\text{Sp. gr.} \times (100 - \text{Hematocrit})]}{1.0971}$$

The relationship between specific gravity of whole blood and the hematocrit, red blood cell count, and hemoglobin would be expected to be fairly constant. Since, however, the specific gravity of whole blood is partly dependent upon the specific gravity of the plasma, there should be some departure from this relationship when this latter factor is not taken into account. For practical purposes, in spite of this, the hematocrit, red blood cell count, and hemoglobin bear a distinct mathematical relationship to, and can be fairly accurately estimated from, the specific gravity of the whole blood. The relationship between these is shown in Figs. 1, 2, 3. This relationship between specific gravity of whole blood and the hematocrit, hemoglobin, and red cell count may be expressed as follows:

$$(1) \text{Hematocrit} = (\text{Sp. gr. whole blood} - 1.0457) \times 1,000 + 32.$$

$$(2) \text{Hemoglobin} = (\text{Sp. gr. whole blood} - 1.0470) \times 386 + 11.$$

$$(3) \text{Red blood cell count in millions} = (\text{Sp. gr. whole blood} - 1.0466) \times 14.5 \div 3.5.$$

Fig. 1.

Fig. 2.

Fig. 3.

Naturally these equations will yield results slightly in error of the actual values, but these variations do not exceed the limits of technical error by any appreciable extent. Because of this rather accurate correlation between the specific gravity of whole blood and hematocrit, hemoglobin, and red blood cell count, it would seem that they are more or less uniformly efficacious as indicators of hemoconcentration. The value of these studies of peripheral blood as measures of hemoconcentration and relative blood volume change has been further accentuated by recent studies of Ebert and Stead⁷ which showed the relative constancy of circulating red blood cell volume in human beings under various circumstances.

TABLE II

HEMOCONCENTRATION STUDIES IN DOGS IN WHICH SHOCK WAS INDUCED BY INTRAPERITONEAL INJECTION OF HYPERTONIC SALINE (25%)

4	Control	5.03	12.35	36.0	6.56	1.0500				
	Shock	7.95	17.9	51.5	6.7	1.0642	3.6	43	45	58
5	Control	6.37	17.15	48.5	6.39	1.0610				
	Shock	9.63	23.15	70	7.28	1.0749	14.1	44.3	35	51

Table II represents hemoconcentration studies in five dogs in which shock was induced by intraperitoneal injection of hypertonic saline. The percentage increase of hemoglobin, hematocrit, and red blood cell count from control studies to shock values demonstrates the relative efficiency of each method of determining hemoconcentration. It will be seen that fairly accurate correlation in the values was obtained. Protein concentration was estimated from the specific gravity of the plasma according to the method of Weech, Reeves, and Goettseh.⁸ A comparison of the percentage change of protein concentration from control to shock values with corresponding values of other measures of hemoconcentration shows the lack of efficiency of protein concentration as a measure of hemoconcentration or relative blood volume change. This is to be expected, since proteins are lost from the circulating blood during the development of shock.

SUMMARY

1. The average specific gravity of normal human erythrocytes is 1.0971. This factor is fairly constant in different persons, but in anemia there frequently is a greater departure from the average than in normals.

2. The hematocrit may be calculated from the specific gravity of whole blood and of plasma in human beings. Also a fairly accurate estimate of red blood cell count, hemoglobin, and hematocrit may be made from the specific gravity of whole blood alone, since these values bear a constant relationship to one another.

3. Specific gravity of whole blood, hemoglobin concentration, hematocrit, and red blood cell count are uniformly efficacious as indicators of hemoconcentration and relative blood volume change.

4. Protein concentration or specific gravity of plasma is not a satisfactory indicator of hemoconcentration during the course of shock, since protein is lost from the circulating blood.

INDOLURIA IN RHEUMATOID ARTHRITIS*

EUGENE NEUWIRTH, M.D., NEW YORK, N. Y.

INDOLE is formed by bacterial action upon protein. This action may take place in the gastrointestinal tract, the urinary tract, or in some focus of infection.³ Normally, indole is oxidized in the body to indoxyl, which is conjugated with potassium hydrogen sulfate, with the formation of indican that is excreted in the urine. The indoxyl detoxifying mechanism is located in the liver.

In normal persons under normal conditions, free indole does not appear in the urine. In over 100 determinations on normal persons, urinary indole was found in only one, and then only upon one occasion.⁴ On the other hand, indoluria was encountered in various pathologic conditions.^{2, 4}

Vaughan¹¹ was unable to detect the presence of indole in specimens of urine from diseased persons. However, Vaughan,¹² and Carnes and Lewis,³ point to the possibility that the urine may contain a substance that might be converted into indole by the action of *E. coli*. These investigators observed that indole-negative urines may become positive upon standing.

Deficient oxidation, impaired liver function, sulfur deficiency, excessive indole production in the intestinal tract, and many other concepts were advanced as theoretical possible causes for the appearance of free indole in the urine.^{2, 4}

*This study was conducted from February 2 to July 15, 1938.

Received for publication, June 18, 1941.

Forbes and Neale⁴ reported indoluria in a variety of pathologic conditions, including rheumatic fever, gonococcal, infectious, rheumatoid, and hypertrophic arthritis. These investigators used steam distillation in the presence of tartaric acid, followed by colorimetry, to determine quantitatively the indole in the urine. Values less than 0.05 mg. per liter of urine were regarded as a trace. Most cases ran from 0.5 to 1.5 mg. per liter of urine.

As indoluria might be evidence of the liver failing in its detoxifying action, possibly because of sulfur deficiency, it seemed logical to Forbes and Neale and their collaborators⁵ to give patients with chronic arthritis a diet that contained a high proportion of sulfur amino acids. It was noted that clinical improvement was accompanied by a decrease and eventual disappearance of the indoluria.

In contrast, it seemed improbable to Basinski and Lewis² that indoluria should be related to a lack of sulfur needed for conjugation. In their patients having indoluria, the cystine level in the fingernails was found to be normal.

The demonstration of indoluria in patients with rheumatoid arthritis by Forbes and Neale,⁴ prompted me to test the urines of 88 patients with rheumatoid arthritis for the presence of free indole. The patients, consisting of 46 females and 42 males, were partly from my private practice, partly from the People's Hospital at Pistany Spa, Czechoslovakia. This hospital, equipped with 600 beds, is dedicated to the treatment of panel patients suffering from chronic arthritis and other rheumatoid conditions. The patients stayed three to four weeks at the hospital, the average duration of the "spa cure." The spa treatment consists of the use of naturally hot sulfur springs and of the sulfur-containing mud of volcanic origin, the latter being administered in the form of mud baths and packs. The rationale and technique of the spa treatment were described in a previous article.¹⁰

Considering that sulfur is absorbed through the skin,^{3, 7, 8} and that its absorption had been demonstrated from the mud applied to the shaved skin of a rabbit,⁶ I attempted to investigate not only the presence of free indole in the urines of patients with rheumatoid arthritis, but also its fate in the urine of patients who take a "spa cure." However, I was unable to complete the latter part of my study.

The samples of urine, obtained from the patients at any hour throughout the day, and at any period in the course of the spa treatment, were collected as follows: After the glans penis and the urethral orifice of the male patient had been washed, the urine was collected in two portions. The first specimen of urine was discarded, the second one was collected in a sterile container and promptly tested for indole. The female patients cleansed their external genitals, and voided into two containers, the second of which was sterile and its contents were used for indole determination, which analysis was made within thirty to sixty minutes. The method of analysis used by Forbes and Neale⁴ was employed in the study on indoluria.

The analytical results of the examined urine specimens obtained from 88 patients with rheumatoid arthritis were as follows: In the 46 females, the values of indole were between 0.3 and 1.8 mg. per liter of urine; in the 42

males, the indole values were between 0.2 and 1.94 mg. per liter of urine. Less than 1 mg. of indole per liter of urine was found in 32 females (69.6 per cent), and in 31 males (73.8 per cent). More than 1 mg. of indole per liter of urine was found in 14 females (30.4 per cent) and in 11 males (26.2 per cent).

The results reported here are in agreement with those of Neale⁹ who, recently, in a series of 50 cases of proliferative arthritis in female patients obtained urine aseptically by catheterization and demonstrated free indole in urine which was shown to be sterile by culture. This indoluria disappeared when the patients responded to treatment.

SUMMARY

Free indole was shown to be present in the freshly voided urine samples obtained from 88 patients with rheumatoid arthritis. These results confirm the observations reported by Forbes and Neale.⁴

I wish to acknowledge the cooperation of Dr. Anna Igumova, Head of the Chemical Research Laboratory at Pistany Spa. I gratefully offer an expression of appreciation to her.

THE IODINE CONTENT OF BLOOD, URINE, AND SALIVA OF NORMAL PERSONS IN THE NEW YORK CITY AREA*

MAURICE BRUGER, M.D., J. WILLIAM HINTON, M.D., AND WALTER G. LOUGH, M.D.
NEW YORK, N. Y.

SINCE the numerous studies on the iodine content of body fluids have been adequately reviewed in the recent books by Elmer,¹ McClendon² and Salter,³ only the pertinent literature will be referred to in this report.

MATERIAL AND METHODS

Blood, urine, and saliva were obtained from 22 normal persons of whom 9 were males and 13 were females. Their ages ranged from 13 to 51 years. The usual hospital personnel (physicians, nurses, technicians, etc.) served as a major source of material but those assigned to surgery were uniformly excluded because of probable contact with iodine. No attempt was made to standardize the antecedent diet. All materials used for the collection of specimens, such as syringes, needles, and containers, after thorough cleansing, were rinsed with iodine-free distilled water. Iodine-free alcohol was used to sterilize the skin prior to venipuncture.

Urine collections were made over a twenty-four-hour period; blood and saliva were obtained usually after breakfast, and approximately twelve hours after the collection of the urine was begun. The method of Trevorrow and Fashena⁴ was used throughout.

RESULTS

The results are given in Table I. The total blood iodine ranged from 3.1 to 8.4 micrograms per 100 ml. of whole blood, with a mean of 5.9 ± 1.3 . The concentration of iodine in the urine varied from 6.2 to 56.7 micrograms per 100 ml., with a mean of 21.1 ± 16.7 . The total output of iodine in the urine for twenty-four hours ranged from 18.0 to 483.1 micrograms, with a mean of 190.8 ± 138.0 . The salivary iodine varied from 3.5 to 24.0 micrograms per 100 ml., with a mean of 10.2 ± 5.1 .

DISCUSSION

It is generally appreciated that the normal range for blood iodine reported by some of the earlier investigators is undoubtedly too high. Riggs and Man⁵ have recently analyzed critically the various procedures and have pointed out the discrepancies inherent in the older methods of chemical analyses. The comparatively high normal values recorded in the literature may further be ascribed to the selection of persons who inadvertently ingested iodine or who were ex-

*From the combined Medical and Surgical Thyroid Clinic and the Medical Research Laboratory, Department of Medicine, New York Post-Graduate Medical School and Hospital, Columbia University, New York.

Received for publication, July 9, 1941.

posed to it in some form. Greene and one of us (M. B.)⁶ have stressed this point. In the present series, the average concentration of 5.9 ± 1.3 micrograms of iodine per 100 ml. of whole blood agrees closely with the findings of some recent investigators⁷ and is slightly higher than that recorded by another group.⁸

Baumann and Metzger^{8c} maintained that the blood iodine of males was higher than that of females, an observation which was not confirmed by Fashena,^{7b} Turner and co-workers,^{7c} and Riggs and Man.⁵ The present studies are in agreement with the latter group. The average blood iodine in the 9 males was 5.7 micrograms per 100 ml. and in the 13 females, 6.0 micrograms per 100 ml.

TABLE I

THE IODINE CONTENT OF BLOOD, URINE, AND SALIVA OF NORMAL PERSONS

SUBJECT NO.	AGE	SEX	BLOOD IODINE ($\mu\text{g}/100 \text{ ml.}$)	URINE			SALIVARY IODINE ($\mu\text{g}/100 \text{ ml.}$)

Range			3.1-8.4		6.2-56.7	18.0-483.1	3.5-24.0
Mean			5.9		21.1	190.8	10.2
Standard deviation			± 1.3		± 16.7	± 128.0	± 5.1

The excretion of iodine in the urine of normal individuals varies directly with the intake of iodine in food and water. The urinary loss of iodine, therefore, is dependent upon the geographic location. In goitrous regions the excretion of iodine in the urine is approximately 50 micrograms or less in twenty-four hours.⁹ In the New York City area, where food and water are iodine rich, the present study shows a wide range in the excretion of iodine. The average iodine loss in the urine in the 22 normal persons was 190.8 ± 138.0 micrograms in twenty-four hours.

In contrast to the large number of studies recorded in the literature on blood and urinary iodine, few investigations have been carried out on the concentration of iodine in the saliva.¹⁰ Schneider and Widmann^{10b} reported that the salivary iodine may vary from 0 to 362 micrograms per 100 ml., but this range is altogether too wide. In view of the results obtained in the present

studies, some of their subjects were probably ingesting abnormal amounts of iodine. The range observed in the 22 normal persons in this series was 3.5 to 24.0 micrograms per 100 ml. of saliva, with an average of 10.2 ± 5.1 .

CONCLUSIONS

1. The concentration of iodine in whole blood of 22 normal persons in the New York City area varied from 3.1 to 8.4 micrograms per 100 ml., with a mean of 5.9 ± 1.3 . In 9 males the mean was 5.7 micrograms per 100 ml. and in 13 females, 6.0 micrograms per 100 ml.

2. The concentration of iodine in the urine varied from 6.2 to 56.7 micrograms per 100 ml., with a mean of 21.1 ± 16.7 . The total output of iodine in the urine in twenty-four hours varied from 18.0 to 483.1 micrograms, with a mean of 190.8 ± 138.0 .

3. The concentration of iodine in the saliva varied from 3.5 to 24.0 micrograms per 100 ml., with a mean of 10.2 ± 5.1 .

We are grateful to Samuel Member, B.S. for valuable technical assistance.

LABORATORY METHODS

GENERAL

MECHANICALLY RECORDING BLOOD SEDIMENTATION CURVES*

IRA R. MORRISON, M.D., ATCHISON, KAN.

ALTHOUGH credit for discovery of the blood sedimentation test is given to the ancients, the test has been in vogue only since it was accidentally re-discovered in 1918 by the Swedish gynecologist, Robin Fahraeus, in his search for a blood test for pregnancy. Since then no less than forty different techniques have been suggested to perform this very simple test. A standard method would certainly enhance its clinical value.

During recent years efforts have been made by several investigators to record mechanically the blood sedimentation phenomenon. Up to the present three such methods have been devised. These three methods are fundamentally alike in that they are based on the principle that light, which will penetrate plasma, is obstructed by the red blood cell column. The first method devised was the silhouette method. Litten, of Germany,¹ in 1929 exposed a tube of sedimenting blood to a light source. The tube was placed in a slot in front of a kymographic drum, which carried light sensitive paper upon which the increasing column of plasma was recorded as the exposed area of the paper, the lower border of the exposed area revealing the blood sedimentation curve. Sulkowitch² devised a very similar instrument in 1934. In 1938 a second method was presented by Lee,³ who published an article describing the camera method for recording blood sedimentation curves. His device makes use of a lens situated between the blood tube, which is placed in a slot in a light-tight box, and a moving photographic plate which records the image of the illuminated plasma. Nichols⁴ reported a similar device with an added improvement of a thermostatic compartment to maintain the blood at normal body temperature. A third method, which as yet has not been published, makes use of a photoelectric cell, exposed to light coming through the blood plasma. The instrument is so designed as to cause the photoelectric cell to move downward with the lower level of blood plasma. This movement in turn operates a pen which records the sedimentation curve as an inked line on paper carried by a kymographic drum.

I have made use of all three of these methods and, in my hands, the simple silhouette method, combined with a thermostatically controlled compartment to maintain the blood at a normal body temperature, proves most satisfactory. The camera method has the disadvantage of making use of an optical system, which

*From the University of Kansas Medical School Department of Internal Medicine, Kansas City.

may make for a source of error not easily detectable. The photoelectric cell method has the distinct advantage of requiring no darkroom technique, inasmuch as the curve is written on paper with an ink tracing, but with this instrument one cannot be sure that the tracing is correct unless one knows that the line of demarcation between plasma and blood cells is definite. With either of the photographic methods, a hazy line of junction will show up as a hazy line, whereas the photoelectric cell method will show up as a sharp line of demarcation regardless of whether or not the zone of junction is clear.

Fig. 1.—Side view of a sedograph with tube in place. The light source compartment has been opened to show the neon tube and transformer. The recording chamber at the right is partly opened, showing the drum.

It has been the common practice of those working with mechanical methods of recording blood sedimentation curves to use the one-hour techniques, especially the Cutler method, probably because it is a well-standardized procedure. I feel that in this point they have been in error. Although the sixty-minute recordings are good methods of ascertaining sedimentation rates when readings are recorded by a laboratory worker, time consumed being a factor, if a machine is to do the test one may just as well see the entire curve without loss of time, and not only a part of the curve as is revealed by the one-hour technique, especially for the bloods of slower sedimentation rates. For instance, two different blood samples which manifest a sedimentation of 5 mm. at the end of one hour in a Cutler tube will also fall 5 mm. in our tube that requires a 30 cm. blood column, because with this slight degree of sedimentation the packing stage influence is not felt. But after the first hour the course of the sedimentation curves of the two bloods may be very different, one sample sedimenting slowly, and the other rapidly. The presedimentation stage is not influenced by the length of the tube. Note in the second sedograph (Fig. 2) that the presedimenta-

tion period requires the entire first hour. Beyond that time the fall may take a slow or a rapid course that can only be determined by reading over a period of time longer than one hour. The longer the tube and time of observation, the more tedious the test but the more accurate the results. Blood samples reveal-

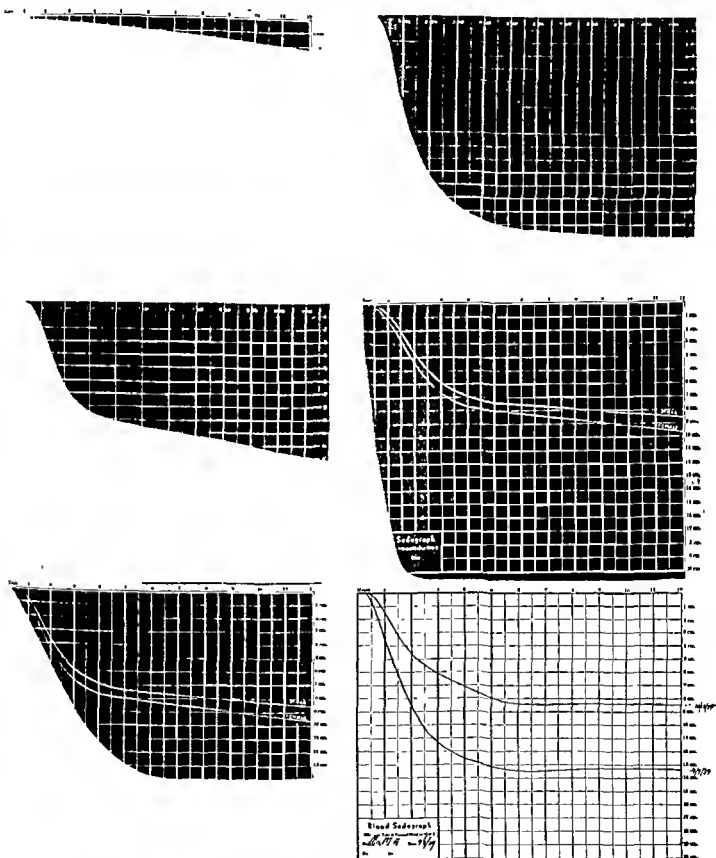

Fig. 2.—Five sedograph records showing different types and degrees of sedimentation curves. In the right lower corner is a piece of tracing paper upon which have been traced two curves from the same individual.

ing identical curves using the one-hour Cutler method have produced unlike sedograph records, one well within the limits of the normal, and the other definitely pathologic.

The silhouette method instrument for recording blood sedimentation at normal body temperature is a device to which I have given the name "sedo-

graph." It is a metal box 5 by 11 by 14 inches, and is divided into three vertical, parallel compartments. In one end compartment is a mercury vapor tube that acts as a light source; in the other end compartment is a slowly revolving drum that carries light sensitive paper which is held in place on the drum by a transparent film mask. On the mask are parallel, horizontal, and vertical black lines, 1 cm. apart, registering as white calibrations the hours of exposure and the centimeters of blood plasma on the final image. The middle compartment contains the blood tube. This compartment is equipped with a heating unit and a thermostatic control which maintains the compartment and the blood tube at

Fig. 3.—Lateral diagrammatic drawing of the sedograph instrument, showing the recording chamber on the left, the light source chamber on the right, and the blood-containing thermostatic-controlled chamber between the two.

a temperature of 99.6° F., thus imitating in vivo conditions. Contrary to general opinion, room temperature is a variable which must be taken into consideration if we are desirous of obtaining exact information from blood sedimentation. Room temperature may vary as much as 30° F. in certain parts of the country, which is too great a change to be disregarded if an accurate record is desired. In some bloods I have found sedimentation rates at 100° F. to be as much as doubled what they are at 70° F. To maintain constant temperature, we have found it simpler to use a heating system that will raise the blood above the outer limits of room temperature, rather than to install a cooling system.

The temperature in the thermostatic compartment is controlled by a wafer thermostat and two 25-watt electric light bulbs which cycle on and off, maintaining constant temperature. This type of thermostational arrangement is used because I have found it to be the one that gives the least lag and the least overshoot at the onset of the test. There is a time interval of about six to ten minutes, depending upon the temperature of the room, during which the thermostational compartment is warming up to blood temperature. Inasmuch as this is the presedimentation period, I feel that it is unnecessary to warm the compartment by inserting an empty tube into the apparatus just prior to the test.

The records make use of $8\frac{1}{2}$ by 11 inch photographic paper, since this is the size paper most commonly used in hospital charts. This produces an accurate, permanent, actual size image of the sedimentation progress, with more detailed information than do smaller images. This instrument uses ordinary double weight glossy photographic paper, Azo No. 3.

A column of citrated blood 300 mm. in length is used, inasmuch as this is the greatest column of citrated blood that can be accommodated by $8\frac{1}{2}$ by 11 inch paper in those cases with increased sedimentation rates. The length of the tube is a guard against deviation from a strictly upright position, the importance of which has been pointed out by numerous investigators. It is more difficult to be sure that the shorter tubes are perpendicular. We use a tube of 4 mm. inside diameter; tubes of larger diameter transmit the required amount of light with difficulty. This is a convenient sized tube to handle and clean.

The test is run for a period of twelve hours, since sedimentation in a tube of this size is complete for most pathologic bloods by that time, whereas the nearer normal pathologic bloods are seldom complete, and the normal blood samples are never completed in a shorter period of time. I feel that it is very desirable to secure the entire sedimentation curve in order to evaluate properly the results of the test.

I have used 3.8 per cent aqueous sodium citrate as an anticoagulant because it is isotonic with the blood and gives a clearer plasma than heparin or the oxalates, which in the case of my technique is a distinct advantage.

A blue light source is used because, with the pale yellow media of the blood plasma and the opaque red cell volume, a more contrasting image is assured.

The technique of the test is as follows:

Four cubic centimeters of blood secured by venepuncture are mixed with 1 c.c. of 3.8 per cent aqueous sodium citrate in an ordinary test tube. The blood is pipetted to the black mark encircling the 4 mm. diameter sedimentation tube, which gives a column of blood 30 cm. long. A cork is placed in the bottom of the tube, and the tube is inserted into the machine. As the tube is placed in the machine, a switch is automatically closed; this starts the synchronous motor that rotates the drum, turns on the mercury vapor tube, and sets into operation the thermostatically controlled compartment. The test from then on is entirely automatic, including an automatic stop after twelve hours, until such convenient time after twelve hours that the operator may choose to remove the tube, take the machine into the darkroom, develop the record, and reload the machine to await the next test.

A simple and easy method of loading and unloading has been devised, and although our mechanism requires a darkroom for these two operations, which

are done in one sitting, I feel that inasmuch as the instrument is not heavy or bulky, the method is technically simpler than if photographic plates were used, because in either case a trip to the darkroom is necessary. The recording chamber is opened by lifting the dial knob, allowing the recording chamber end, which is hinged at the bottom, to swing open. The film mask is opened by disengaging the rubber bordered ends from their hooks, and the photographic paper is slipped under the mask. The chamber door is closed, and the dial is set at the arrow or "start line." The instrument is now ready to be used again.

The entire instrument consumes about 50 watts of electrical power. The synchronous electrical motor operating the drum makes one revolution in fifteen hours. The greatly reduced speed of the electrical motor makes it powerful and dependable. Twelve hours are used for the operating time, the space of the three remaining hours (6 cm.) being used for attachments of the mask and margins of the paper. The drum is 30 cm. in circumference; therefore, a point on the circumference of the drum moves 2 cm. each hour.

The size of the sedograph record, besides permitting attachment to hospital charts, lends itself well to being traced. A sheet of semitransparent tracing paper may be laid over the sedograph record and the curve traced thereon. Serial sedograph curves of a patient may be traced on this same sheet. It becomes a simple matter then for the physician to see at a glance a mechanically made, complete, and accurate sedimentation curve, as well as the most minute differences in serial readings.

I believe that the future will reveal the necessity of this degree of accuracy.

A SEMISOLID DOUBLE SUGAR MEDIUM FOR THE IDENTIFICATION OF THE COLON-TYPHOID GROUP*

SAMUEL H. ZIA AND P. Y. LIU, PEKING, CHINA

RUSSELL'S double sugar medium has been used extensively in bacteriologic practice. By the use of this single medium, it is possible to obtain preliminary information of practical value in laboratory diagnosis. But its general application is limited, owing to the lack of differentiation between the motile *Eberthella typhi* and the nonmotile *Shigella* group, as well as between the motile *Salmonella* and the nonmotile para-colon group of organisms. Moreover, one of us has shown (P. Y. L.)¹ that it is unnecessary to employ both lactose and dextrose in both the slant and the butt, because the purpose of differentiation can be satisfactorily accomplished by using dextrose alone in the butt and lactose alone in the slant.

Since 1938 we have employed a double sugar medium with a semisolid butt to indicate motility. Acid fuchsin has been used as an indicator since Cummings² has shown that this will give satisfactory results. Over 12,000 specimens of stool alone were examined in the past two years by this medium for preliminary identification. A total of over 2,000 positive cultures of various pathogenic gram-negative intestinal organisms was obtained. The following is the formula of this semisolid medium:

Solution A—Sugar-free broth (blood digest broth ³), pH 7.4	100
Agar	0.35
Solution B—Sugar-free broth, pH 7.4	100
Agar	0.9
Lactose	1.0

Sterilize both solutions A and B by autoclave at 8 pounds pressure for fifteen minutes and cool to about 60° C.; add to both solutions A and B 0.5 c.c. of 2 per cent aqueous solution of acid fuchsin.

Keep solution B in water bath at 45° to 50° C. until used.

To solution A add 2 c.c. of a sterile 10 per cent solution of dextrose.

Fill tubes of 12 mm. inside diameter with 2 c.c. of solution A and cool in upright position until it solidifies. Then add to the same tubes solution B also in 2 c.c. amounts and let it solidify in a slanting position. The medium is now ready for use.

ACTUAL PROCEDURE AND INTERPRETATION

The stool specimens are, as usual, plated on the China blue rosolie acid medium, which in our hands have given satisfactory results. Next morning, after

*From the Department of Bacteriology and Immunology, Peking Union Medical College, Peking, China.

Received for publication, September 26, 1940.

sixteen to twenty hours' incubation, each of several suspicious colonies picked from every plate is inoculated into a tube of this semisolid double sugar medium. After another twenty-four hours' incubation the results in this medium are read and interpreted according to the scheme in Table I.

TABLE I

RESULTS IN SEMISOLID MEDIUM				TENTATIVE DIAGNOSIS
Slant	Fermentation in Butt	Gas	Production of Motility	
O	A	-	-	<i>Shigella</i>
O	A	-	+	<i>Eberthella</i>
O	A	+	+	<i>Salmonella</i>
O	A	+	-	Para-colon group
A	A	+	+ or -	Colon-aerogenous group
O	O	-	+	<i>Alkaligenes</i>

O = No change. - = Nonmotile or no gas production.

A = Red-color. + = Motile or positive for gas.

For those cultures that show the first three types of reaction, further transfers into sugar fermentation tubes and agglutination with specific serum are made. Cultures showing the latter three types of reaction were discarded and considered to be those of nonpathogenic organisms. Care should, however, be exercised in cultures giving the type of reaction of the para-colon group, since the nonmotile *Salmonella* would give the same reaction. In such cases the amount of acid produced may give some indication, since the organism of the para-colon group usually produces a large amount of gas. If the amount of acid produced is slight, further studies in special sugars are indicated.

COMMENTS

The medium herewith reported makes use of the original principle of Russell's medium but has the following additional advantages:

- (1) The consistency of the butt is sufficiently hard to stand up under the slant and at the same time is suitable for the demonstration of motility.

The use of an inexpensive and stable indicator—acid fuchsin.

The elimination of one of the sugars from both butt and slant, found unnecessary, effects material economy when large numbers of stool cultures have to be examined daily.

- (4) Blood digest medium has been found to be sugar free and to support growth for the organisms examined without the addition of peptone.

DECREASED FRAGILITY OF ERYTHROCYTES INTERFERING WITH LEUCOCYTE COUNT*

MILTON G. BOHRD, M.D., MIAMI BEACH, FLA.

INCREASED resistance of erythrocytes to hypotonic solutions occurs infrequently. It is known to be a transitory phenomenon in hypochromic anemias, particularly after the loss of a large amount of blood, in some cases of obstructive jaundice and in pneumonia. The discovery of such decreased fragility requires the special technique of the commonly used fragility test. Whether cells more resistant than usual to hypotonic solutions are more resistant to other hemolytic agents has not been definitely determined. The following case is reported to illustrate the possibility of increased resistance of erythrocytes to acetic acid to the point where it interfered with the routine technique for counting leucocytes. The circumstances surrounding the discovery of this unusual phenomenon are as follows:

The patient was a 31-year-old woman, gravida iv, who had a breech extraction of a premature dead fetus (twenty-six weeks' gestation) on August 10. The placenta separated slowly and with difficulty, and there was considerable loss of blood. Her red blood cell count dropped in two days to 2,180,000, while she continued to pass blood clots from the vagina. In spite of transfusions on August 12 and 13, the erythrocyte count dropped to 1,820,000 on August 14. The color index varied between 1.01 and 1.05. Leucocyte counts were performed on August 12 and 13 (20,600 and 12,600), and nothing unusual was noted while doing these tests.

On August 14 the laboratory technician reported that she was unable to do a leucocyte count because of a large amount of what looked like debris in the counting chamber. Thinking she might have used a solution with precipitate of some kind in it or a dirty pipette, she attempted the count a second time with freshly made solutions; she obtained the same result. A third attempt still showed debris. In the meantime the solution had been used without difficulty on many other patients. The next morning, August 15, she was still unable to count the cells. At this time, examination of the debris suggested that it might be made up of clumped and distorted erythrocytes, and several rough tests were performed to test this hypothesis.

Blood was drawn from the vein, and enough sodium citrate was added to prevent clotting. A drop of this blood when added to the 1 per cent acetic acid usually used for leucocyte counts gave a rather muddy precipitate, and microscopic examination of this precipitate showed clumped red blood cells which could, however, be separated by pressure on the cover slip. A drop of blood was placed in 2 c.c. of 0.85 per cent sodium chloride solution. The red blood cells, for the most part, appeared perfectly normal microscopically, but a few of them were bowl shaped. A drop of blood was placed in 2 c.c. of distilled water. Many cells, of course, hemolyzed; but some cells did not hemolyze even after about fifteen minutes, and examination of these unhemolyzed cells showed nearly every one to be bowl shaped instead of the usual biconcave disc. Since this type of cell has been described¹ and shown to have decreased fragility or increased resistance to hypotonic solutions, it seemed possible that the cells in this case might also be abnormally resistant to acetic acid. Accordingly, attempts were made

*From the Pathology Laboratories, Methodist Hospital of Central Illinois, Peoria, Ill.
Received for publication, September 30, 1940.

to count leucocytes using stronger solutions instead of 1 per cent acetic acid. With 2 per cent acetic acid a small amount of debris was still noted, enough to interfere with a reliable leucocyte count; with 3 per cent acetic acid used as diluting fluid, the field was clear and a leucocyte count could be made without difficulty. During the remainder of the patient's stay in the hospital white blood cell counts were made daily, using both 1 per cent acetic acid and 3 per cent acid as diluting fluids. On August 16, 3 per cent acid was required, but on August 17 and on succeeding days, it was possible to make the leucocyte count with the usual 1 per cent acid.

In the meantime the patient's erythrocyte count rose slowly, and on August 22 she was discharged from the hospital with a count of 3,200,000. The patient's blood type was type O.

Only a few additional tests were performed in the interval during which the increased resistance to acetic acid was demonstrable. The fragility test was inconclusive, for it was not read until twelve hours after its performance, and it is possible that if it had been read earlier it might have shown more striking results. On August 16 hemolysis was begun at 0.44 per cent sodium chloride and was complete at 0.32 per cent, a result not strikingly different from the normal and one which was not expected after the experiments with distilled water. Before the patient's discharge from the hospital a second test demonstrated hemolysis to begin at 0.46 per cent and to be complete at 0.36 per cent. Hence while the first test was at the lower limit of normal, there was a striking shift simultaneous with the change in resistance to acetic acid.

A galactose tolerance test was normal. The icterus index was 3, and cholesterol in the blood was 205 milligrams per cent.

The fragility of erythrocytes seems to be correlated with the shape of the cell. It is possible to devise a purely mechanical explanation which, at first glance, seems to fit the facts; but there seems to be some doubt as to whether this type of explanation is completely satisfactory. A spherical cell should be able to swell only slightly without disruption, and consequently will hemolyze in slightly hypotonic solutions. The normal biconcave disc can perhaps be conceived of as a partially collapsed cell and should have a greater capacity for taking up fluid than the spherical cell; this, of course, is exactly what happens. A bowl-shaped cell, such as that described by Barrett,¹ should have an even greater capacity for absorbed fluid and, therefore, a greater resistance to hypotonic solutions. The experiments of Barrett seem to show that these cells are resistant to 0.30 per cent sodium chloride and even lower concentrations, and my rough experiments with distilled water in this case seem to bear out this supposition.

The resistance of the cell to acetic acid, however, cannot be explained easily on this purely mechanical hypothesis and suggests that while the shape of the cell is definitely of importance, the physical and/or chemical structure of the cell also varies and is of importance. It is desirable that we know whether resistances to acid and to hypotonic solutions are parallel. The older work seems to indicate that resistance to hypotonic solution and to other hemolytic agents are parallel,² but Dameshek and his co-workers³ suggest that there may be "differential fragilities." Mason and Rockwood⁴ found fragility to any hemolytic agent to vary with the hydrogen-ion concentration. Furthermore, the possibility of the reversal of hemolysis,⁵ as well as other experiments, suggests that rupture of a cell is not even a necessary part of hemolysis.

The bowl-shaped cell described assumes a peculiar form in dried smears, known as the target cell.¹ This is due to a characteristic indentation which takes

place during the drying of the cell, so that there is a central zone of hemoglobin-containing material, a midzone of little or no hemoglobin, and a peripheral zone again of hemoglobin. In our case, about 1 per cent of the cells in dried stained smears show this characteristic target appearance.

Inquiry among our technicians disclosed two previous instances in our laboratory in which it was not possible to perform the leucocyte count because of "debris." In both cases the phenomenon was transitory, lasting in one case one day, in the other, two days; but nothing was done to trace the cause of the phenomenon in these previous cases. The transitoriness of the increased resistance to acetic acid suggests that it may often be missed when repeated leucocyte counts are not performed.

SUMMARY

A case is reported in which, for a period of three days, it was not possible to perform a leucocyte count using the usual 1 per cent acetic acid as diluting fluid. It was, however, possible to make this count if 3 per cent acetic acid was used.

The cause for the difficulty in performing the leucocyte count was the marked increased resistance of the erythrocytes to acetic acid. The erythrocytes were also hyperresistant to hypotonic salt solution, and for a short time some of them were not hemolyzed even by distilled water.

The hyperresistant cells were bowl shaped in wet smears. Probably corresponding to these, target cells were noted in dry smears.

AN AID IN THE INJECTION OF THE EAR VEIN OF THE RABBIT

E. E. BEOHM, A.B., PHILIPPI, W. VA.

VARIOUS means have been advocated for facilitating the injection of solutions into the ear veins of the rabbit, such as removing the hair, placing a paper clip on the ear, rubbing with xylol, and holding the rabbit in a box. All these procedures are of some help, but they leave much to be desired in certain cases.

FIG. 1.

A simple arrangement that we have used in this laboratory for over three years, and that has proved very satisfactory, consists essentially in the use of a light placed below the rabbit's ear. All the veins stand out in view, so that one can be sure the needle is in, and by watching the blood being pushed back by the injected fluid can be certain that the solution all goes in the vein and not out into the tissues.

A light unit attached to the rabbit box makes a compact assemblage ready for use at any time. However, a spotlight bed lamp, which can be obtained at almost any hardware or department store, works very well. It can be clamped to the edge of the table so that the rabbit's ear can be held out over the lens. Fig. 1 shows this type of lamp in use, together with the light unit referred to above detached from the box.

*From the Laboratory of the Myers Clinic, Philippi.
Received for publication, October 10, 1940.

Some rabbits will remain quiet with little or no restraining and it is an easy matter to get into a vein and to stay in, but it is more particularly for those many other rabbits that are not so docile that this method is most useful. Also, where oft-repeated injections are done, the veins can be kept in better condition by the more easy and accurate venepunctures; furthermore, use is permitted of more and smaller veins.

When a rabbit moves his ears so vigorously that it is difficult to keep the needle in the vein, the needle can usually be kept in position by holding it and the ear of the rabbit together by pressure with the thumb on the hub of the needle against the fingers below the ear, and at the same time pulling slightly on the ear.

COMPOSITION TUBES AS A SUBSTITUTE FOR GLASS IN THE ISOLATION OF SPORULATING ANAEROBES

RONN SPALDING SPRAY, PH.D., MORGANTOWN, W. VA.

EXPERIMENTS have been conducted for some time with the cultivation of sporulating anaerobes in tubes constructed of substances other than glass. Experiments thus far conducted seem to warrant a brief report, together with continued investigation.

The early experiments were conducted with small, spirally wound cellulose tubes, sold widely under the name of "Glassips." These were plugged with cotton at the upper end and sterilized in large glass tubes by baking at 160° C. for three hours. No extensive alteration of the tubes was effected by this heating.

Customary culture dilutions were made in melted tubes of suitable anaerobe agar. Each dilution was drawn up into separate pipettes ("Glassips") to a height of about 10 cm. The lower tip of each pipette was then dipped into a dish of sealing wax kept just above the melting point. These pipette cultures were then incubated at 37° C. as usual.

In these tubes we successfully cultivated *Cl. perfringens* and *Cl. tertium*. *Cl. sporogenes*, a much more strict anaerobe, grew only intermittently, and gave many failures. *Cl. botulinum* type A did not grow in any trial.

While this established the principle, it seems that these very thin-walled tubes do not maintain a sufficient degree of anaerobiosis to warrant their use for the purpose desired.

We next experimented with a larger and thicker-walled tube, sold commercially as a container for toothbrushes. This tube is of test tube construction, and is about 15 cm. in length and 2 cm. in diameter. It is composed, presumably, of some form of cellulose. This tube was plugged and baked. Melted whey agar was inoculated with *Cl. beijerinckii* and poured into the composition tube, hardened, then incubated at 37° C. Within twenty-four hours the colonies were visible to the naked eye.

A control culture in a glass tube showed much more vigorous growth and extensive gas formation, while gas did not appear in the composition tube until after forty-eight hours. It was noted also that, in the composition tube, the colonies developed chiefly in the center of the agar column, not approaching closer than about 2 mm. from the wall of the tube. We presume from this either that the material in the wall of this composition tube is not an absolutely effective seal against oxygen, or that possibly some toxic agent may diffuse slightly from the wall into the medium. The former suggestion is the more probable explanation.

However this may be, the plastic tube served effectively to grow, in a deep agar column, an anaerobic organism which consistently offers difficulty in ordinary plate isolation.

The chief advantage of this proposed method of cultivation is that the colonies may be reached directly through the wall without cracking the tube, as is the usual procedure with glass tubes, or by slipping out the agar column, as is the case with the use of the Burri tube. Both of these methods offer opportunity for contamination unless the tube contains only a single species.

The wall of the composition tube may be washed with suitable disinfectant (it cannot be flamed), and a dissecting needle is heated to red heat. It is then easily and instantly inserted through the wall of the tube opposite the desired colony. A Pasteur pipette tip is heated and drawn to a fine capillary. This tip is snipped off and inserted through the hole into the colony. The semifluid colony contents can be observed to enter the capillary, which is then inserted into a tube of suitable sterile culture medium and tapped to break off the tip.

We are now seeking a variety of sizes of tubulatures of similar resin compounds, and hope to report more extensive experiments in the near future.* Horsfall¹ has recently reported the use of celluloid tubes for the preservation of frozen viruses. We believe that similar composition tubes may offer a new and effective means of anaerobic isolation, as applied especially to certain species which do not respond readily to the usual plating methods.

It may be added that this principle has been applied experimentally to plating, using the original Koch mica sheet cover idea, but substituting flat sheets of cellulose. We must admit that, thus far, the results are only imperfectly successful. Only *Cl. perfringens* and *Cl. tertium* have responded. We believe that thicker sheets of cellulose, together with greater depth of agar in the plates, may give more satisfactory results. At least the preliminary results appear to warrant continuation and modification of the experiments.

*Since acceptance of this paper for publication, tubes and open tubing in a variety of plastic materials of suitable sizes and wall thicknesses have been obtained from the Dow Chemical Company, Tennessee Eastman Corporation, and the Lusteroid Container Corporation. The applicability of these to the problem of anaerobic isolation will be reported upon in a subsequent publication.

INEXPENSIVE SPECIFIC GRAVITY APPARATUS*

HURLEY L. MOTLEY, PH.D., M.D., COLUMBIA, MO.

DURING the past few years the determination of specific gravity by a more accurate technique, such as the falling-drop method of Barbour and Hamilton,¹ has increased tremendously in popularity. In many cases the specific gravity of the blood gives the essential information that much more time-consuming and costly albumin and globulin determinations convey. The method is simple and can be performed readily in a doctor's office in a few minutes, thus obtaining the results without delay and with very little inconvenience for the patient. In the medical school curriculum the student should be taught how to use this equipment, and the significance of such determinations with regard to blood, serum, urine, and body fluids. The chief drawback has been the expense involved in providing the high-priced manufactured outfits in sufficient numbers as routine physiology and pharmacology laboratory equipment for regular classroom use.

An inexpensive satisfactory specific gravity apparatus was devised, using a regular 2 liter unruled graduate cylinder as the container, for this holds sufficient water so that temperature does not fluctuate excessively. Two circular discs of sheet brass, $\frac{3}{16}$ inch thick, were cut to fit the graduate cylinder, with just enough play so that removal from the container was easy. Four holes were drilled into each disc (Fig. 1) for the glass tubes,[†] with a bore between 7.45 and 7.55 mm., as described by Barbour and Hamilton.¹ A central hole was drilled in each just large enough to allow a brass rod, $\frac{1}{4}$ inch in diameter, to pass through. One brass disc was then soldered flush with the end of the brass rod, and the other disc was soldered on the rod so that the distance was $2\frac{1}{2}$ inches from the top of the cylinder, when the first disc was placed on the bottom inside the container. The four holes in each disc were lined up in proper position at the time of soldering, one above the other, so that the glass tubes were held in a true vertical position. The central brass rod was cut off $1\frac{1}{2}$ inches above the upper disc and used as a handle, and the grip was improved by fitting a round nut on the end. Three legs were made from the brass rod and attached to the lower brass disc by drilling proper size holes as close to the outside edge as possible and soldering them in place. Each leg was made an inch long and spaced equally distant, one from the other. Two small holes were drilled in the upper disc, one on each side, between the holes for the glass tubes, each for a

*From the Department of Physiology and Pharmacology, School of Medicine, University of Missouri, Columbia.

Received for publication, October 11, 1940.

†The glass tube should be about 50 cm. long and the bore must be carefully checked at each end and fall within the prescribed dimensions. The tubes are marked with lines that extend all the way around exactly 30 cm. apart, which is the distance used in determining the drop falling time with a stop watch graduated in one-tenth seconds. The tube can be cleaned easier if the lower end is left unsealed and closed with a cork.

long stem centigrade thermometer. A small brass holder with a piece of brass placed through the open ring on the upper end was used to hold the thermometer in place (Fig. 2). Thus the thermometers were placed in a convenient position for reading and for accurate determinations of the temperature. Small brass rings, 1/16 inch wide, were placed around the glass tubes, containing the xylene-brombenzene mixture, exactly 30 cm. apart from inside edges. These

Fig. 1.

Fig. 2.

Fig. 1.—Photograph of stand for holding specific gravity tubes.

Fig. 2.—Photograph of stand in glass graduate containing specific gravity tubes in place.

increased the accuracy of stop watch readings of the drop falling time over plain scratch marks on the glass. All the apparatus placed in the glass graduate (see Fig. 2) can be removed together at once and quickly, which makes cleaning the tubes and refilling easy, or convenient for storing equipment. The rigid support holds the glass tubes firmly and securely in place. There are four tubes containing four different xylene-brombenzene mixtures, thus insuring an adequate range.

A one-handed controlled pipette holder, as described by Guthrie,² has been very satisfactory in this laboratory for use with the special 10 c.mm. pipette for measuring the size of the drop. A good technician can make a perfectly satisfactory holder at a very low cost.

The total cost of parts for this apparatus for the department at Columbia, Mo., was less than \$2.00, exclusive of the labor, stop watch, thermometer, and pipette. The laboratory technician assembled the parts without difficulty. In case of breakage of the glass cylinder, the apparatus could be transferred to another quickly. Using the foregoing method for constructing the apparatus, one such piece of equipment can be supplied each four or five students without excessive cost, and accurate results can be secured for research as well as for teaching purposes. In many instances the specific gravity determinations training would be very valuable, for probably the specific gravity of the blood would be obtained in many cases which otherwise would be neglected if it were necessary to obtain total protein or albumin-globulin determinations.

THE TECHNIQUE FOR THE ISOLATION OF BRUCELLA FROM HUMAN BRUCELLOSIS*

MARY A. POSTON, M.A., DURHAM, N. C.

INTRODUCTION

THE isolation of *Brucella* from human sources offers considerable difficulty. Various methods have been described,¹ all of which must be modified at times, depending upon the source of the material which is being cultured.²⁻⁶ The procedures described here have been developed for routine use in the biologic division of Duke Hospital for the isolation of *Brucella* from blood, bile, lymph nodes, joint fluid, spinal fluid, feces, urine, and necropsy specimens.

METHODS

Blood.—Fifteen cubic centimeters of the patient's blood are introduced into a flask containing 4 c.c. of 2.5 per cent sodium citrate solution. Two cubic centimeters of the citrated blood are added to each of four deep tubes (15 c.c.) of molten liver infusion agar, cooled to 40° C. for pouring plates. Two cubic centimeters of blood are added to each of two flasks containing 100 c.c. of beef infusion broth, pH 7.4. Half of the cultures are incubated in the presence of 10 per cent carbon dioxide.

All cultures are examined daily. After the first forty-eight hours' incubation, if no colonies are visible on the plates, 5 c.c. amounts of the supernatant broth are transferred from the flasks to sterile centrifuge tubes. After centrifugalization at high speed for fifteen minutes, the supernatant fluid is dis-

Received for publication, November 22, 1940.

carded, a loopful of the sediment is streaked over the surface of a liver infusion blood agar plate, and on a slide for a stained smear. The flasks are then shaken to mix the blood and broth, and 10 c.c. of this mixture are transferred to each of two flasks of fresh broth.

The colonies of *Brucella* in a poured plate containing blood resemble those of *Strep. viridans*, if such colonies are deep in the medium. After further incubation, especially if growing to the surface, the colony appearance resembles more closely that of *E. typhosa*. The colonies are picked and streaked over the surface of a liver infusion blood agar plate. The transplants are incubated under the same conditions as the original cultures. This procedure is repeated at two- to three-day intervals, until sufficient growth is obtained for identification. *Blood cultures for Brucella should be kept for eighteen days before being reported as negative.*

After there is sufficient growth, tubes of dextrose, lactose, maltose, mannite, sucrose, and plain beef infusion broth, pH 7.4, are inoculated. A non-motile gram-negative coccobacillus, which ferments none of the carbohydrates and is agglutinated by antibrucella serum is diagnostic of *Brucella*. The bacteriostatic reaction of dyes⁶ and agglutinin-absorption tests⁷ are used to differentiate the species of *Brucella*.

These cultures may be supplemented by the inoculation of 2 c.c. amounts of the citrated blood into the peritoneum of each of two guinea pigs. *The animals are kept for three months if necessary before they are killed.* The spleen, liver, peritoneal fluid, and lymph nodes (if enlarged) of the animals are cultured for *Brucella*.

Bile From Duodenal Drainage.—The "B" bile is used for culture. One-tenth cubic centimeter of bile is added to each of four tubes containing 10 c.c. of beef infusion broth, pH 7.4, and the same amount of bile is streaked over the surface of each of two liver infusion blood agar plates. Half of the cultures are incubated in the presence of 10 per cent carbon dioxide.

The cultures are examined daily after the first forty-eight hours' incubation. If the broth tubes are cloudy, 5 c.c. amounts are transferred to sterile centrifuge tubes. After centrifugalization at high speed for fifteen minutes, the supernatant fluid is discarded, and a loopful of the sediment is streaked over the surface of a liver infusion blood agar plate. A smear of the sediment is made and stained by Gram's method. If the broth tubes are not cloudy, 1 c.c. is transferred to tubes of fresh broth, and after forty-eight hours' incubation, the procedure just described is repeated.

On the streaked plates after twenty-four to seventy-two hours' incubation, the colonies are barely visible to the naked eye, appearing as minute, transparent colorless drops. *Microscopically, these are made up of small noncharacteristic gram-negative bodies, and one not familiar with the growth habits of Brucella may not identify this organism.* However, after transferring to fresh liver infusion blood agar and incubating for twenty-four to forty-eight hours, the colonies are larger and more numerous, and the organism is more typical in the Gram's stain. The transplants are incubated under the same condition as the original cultures. This procedure is repeated at two- to three-day intervals,

until there is sufficient growth for completing the identification. *The cultures should be kept for fourteen days before they are reported as negative.*

Lymph Nodes.—Lymph nodes removed by biopsy are cut immediately into small pieces with sterile scissors. Pieces of the node are streaked over the surface of two liver infusion blood agar, or North's gelatin blood agar, slants, or plates. One slant or plate is incubated in an atmosphere of 10 per cent carbon dioxide. If slants are used, the upper portion of the tube is heated in the flame to expel the air, which is then replaced by blowing the breath into the tube through a sterile plugged pipette, and inserting immediately a sterile rubber stopper. By this procedure a concentration of approximately 10 per cent carbon dioxide is obtained.

The cultures are examined daily. The first evidences of growth are tiny colonies resembling droplets of moisture, which may appear after forty-eight to seventy-two hours' incubation. *Stained smears from these colonies show minute coccoid bodies with indefinite outlines.* Transplants are made to fresh media every two to three days after the first seventy-two hours' incubation, even though there may be no visible growth. After one or two transplants the colonies are larger and stained smears show the usual coccoid or bacillary forms. The organism is identified in the usual manner. *The cultures are kept for three weeks before they are reported as negative.*

The remaining portion of the lymph node is ground in a sterile mortar, to which are added 2 c.c. of sterile physiologic saline. One cubic centimeter of this mixture is injected into the groin of each of two guinea pigs. The animals are followed in the same manner as those injected with blood.

Joint Fluid.—The fluid should be planted at the bedside, and it is essential that the medium used should be warmed to body temperature before it is used for inoculation. Two-tenths cubic centimeter of fluid is streaked over the surface of each of four liver infusion blood agar slants, and the same amount of fluid is put into each of two tubes containing 10 c.c. of beef infusion broth, pH 7.4. Two of the slants are incubated under increased carbon dioxide tension.

The cultures are examined daily, using the same routine as for lymph node cultures. *Cultures of joint fluid are kept for three weeks before they are reported as negative.*

Spinal Fluid.—One cubic centimeter of a 1:100 dilution of inactivated polyvalent antibrucella rabbit serum is mixed with 5 c.c. of spinal fluid and incubated at 37° C. for thirty minutes. After incubation the spinal fluid serum mixture is centrifuged at high speed for fifteen minutes, and 0.2 c.c. of the sediment is planted on each of four liver infusion blood agar slants, and into each of two tubes of beef infusion blood broth, pH 7.4. Two of the slants and 1 tube of broth are incubated under increased carbon dioxide tension.

The cultures are examined daily. The same routine as for lymph nodes is used for the blood agar slants, and the technique for the bile cultures is used for the broth cultures.

Feces.—About 1 Gm. of feces is mixed with 50 c.c. of sterile saline and shaken with a few sterile beads for five minutes. This suspension is filtered through four layers of sterile gauze into a sterile centrifuge tube. If the patient has agglutinins for Brucella in his blood, 0.5 c.c. of his inactivated serum

is added to the filtrate. Diagnostic serum without preservative is used if the patient does not have agglutinins. This mixture is placed in the icebox overnight, and the next morning it is centrifuged at second speed for two minutes. The supernatant fluid is discarded, the sediment is resuspended in 10 c.c. of sterile saline and recentrifuged. This procedure is repeated three times. After the last centrifuging, the sediment is resuspended in 5 c.c. of beef infusion broth, pH 7.4. A loopful of this mixture is streaked over the surface of four eosin methylene blue and two liver infusion blood agar plates. One cubic centimeter of the suspension is put into each of two flasks containing 100 c.c. of beef infusion broth, pH 7.4. Half of the cultures are incubated in the presence of 10 per cent carbon dioxide.

The cultures are examined daily, after the first forty-eight hours' incubation. The colonies of *Brucella* resemble those of *S. dysenteriae* on the eosin methylene blue agar plates. These colonies are transferred to liver infusion blood agar slants. When there is sufficient growth, the organism is identified in the usual manner.

After the first forty-eight hours' incubation, the broth cultures are centrifuged, and the sediment is streaked over the surface of two liver infusion blood agar plates. Each of two flasks are inoculated with 1 c.c. of this sediment, and incubated for forty-eight hours, at which time the procedure is repeated. The transplants are incubated under the same condition as the original cultures. *Cultures of feces for Brucella should be kept for one week before they are reported as negative.*

Urine.—A fresh specimen of urine is centrifugalized at high speed for fifteen minutes. The supernatant fluid is discarded, and the sediment is used for culture. One-tenth cubic centimeter of the sediment is streaked over the surface of each of two liver infusion blood agar plates. One plate is incubated in the presence of 10 per cent carbon dioxide. When present, the organisms grow readily, producing typical colonies containing characteristic coccoid or bacillary forms. After forty-eight hours' incubation, if typical colonies are not present, transplants are made to blood agar plates at two- to three-day intervals. *The cultures are kept for ten days before they are reported as negative.*

Necropsy.—Cultures should be made as soon as possible after death. The surface of the liver, spleen, and kidneys is seared, and a small piece of tissue is removed with sterile scissors (a separate pair of scissors for each organ). If possible, axillary and mesentery lymph nodes are obtained. The small particles of tissue are washed through a series of three Petri dishes containing sterile saline, and then passed through the flame to remove any surface contaminants. The material is ground in a sterile mortar with sterile sand, to which are added 2 c.c. beef infusion broth. One-tenth cubic centimeter of this suspension is streaked over the surface of each of two liver infusion blood agar plates, and incubated in the usual manner. The lymph nodes are cultured as described previously.

The cultures are examined daily and transplants are made at two- to three-day intervals after the first forty-eight hours' incubation. *These cultures are kept for two weeks before they are reported as negative for Brucella.* Guinea pigs are inoculated and followed in the usual manner.

DISCUSSION

The cultures should be examined daily, and transplants of broth cultures should be made to fresh broth at two- to three-day intervals. A Gram's stain of the broth may not be very conclusive, unless the examiner is accustomed to looking at stained smears of the organism. When colonies on solid media first become visible to the naked eye, they appear as minute, transparent, colorless drops on the surface. *Transplants should be made to fresh agar at two- to three-day intervals even though there is no visible growth.* Brucella will not grow on dried agar, so, unless transplants are made to fresh, moist media, the colonies will not increase in size and the organism will disappear. When trying to isolate this group of organisms, it is very important to recognize growth when it first appears and to be able to distinguish between organisms and artifacts in the stained smear.

When organisms are present in small numbers, as in the blood of patients with the chronic form of brucellosis, and in lymph nodes, Brucella may be recovered occasionally from guinea pigs when the cultures are negative.

CONCLUSIONS

The cultural methods for the isolation of Brucella from various parts of the body are described in detail. Especial emphasis is laid upon the necessity of recognizing microscopically the very young forms of Brucella, and upon the study of the cultures for several weeks, if necessary. Disregard of these two factors may result in failure to demonstrate existing organisms.

A NEW OBJECTIVE CIRCULATION TIME TEST (FLUORESC EIN METHOD)*

DAVID B. FISHBACK, M.D., PHILADELPHIA, PA.

A NEW method for estimating the speed of the circulating blood has been done on rabbits and on people. To date, the only reliable simple methods for determining complete circulation time are subjective in nature. A substance is injected into the antecubital vein of the arm, and the time is noted when the patient states that he tastes something bitter, burning, hot, etc., depending upon the substance used. Various substances have been suggested for determining the arm-to-tongue time. Decholin,¹ saccharin,² calcium gluconate,^{3,4} and magnesium sulfate⁵ have been used. One must take into account inaccuracies in such a method. It cannot be used in small children, comatose people, or anesthetized patients. It would, therefore, be more accurate to have an objective method whereby a dye could be injected into the arm and the time noted when the dye appeared in the tongue, eye, etc.

I decided to use a very fluorescent substance, because even in high dilutions the color could be noted by the use of an ultraviolet machine with a filter (Woods filter). The ultraviolet machine was a water-cooled mercury quartz lamp (Kromayer lamp). Young male white rabbits, weighing 6 to 10 pounds, were used. With the rabbit's head projecting through an opening in a box, one assistant injected the fluorescent substance intravenously into the marginal vein of the ear, while another started the stop watch. Then the light switch was turned off, making the room completely dark. The light from the ultraviolet machine was directed toward one of the rabbit's eyes, and the conjunctiva and iris were noted to have a purplish hue. Suddenly a yellow color appeared on the inner margins of the eyelids (conjunctiva), and bright yellow vertical lines spreading into tiny branches were noted in the iris. This occurred simultaneously with a yellow color on the mucous membranes of the lips. There would thus be a sudden sharp end point to stop the stop watch. The time that elapsed between the rapid intravenous injection into the marginal vein of the ear, the passage of the substance through the right side of the heart, to the lungs, back to the left side of the heart, out through the aorta and to the periphery where it was best noted in the eye, was observed.

In rabbits I used the following fluorescent substances: 1 per cent acridine orange, 1 per cent flavophosphine, 1 per cent phosphine, 0.5 per cent acriflavine, 0.4 per cent indigo carmine, riboflavin, and 1, 5, and 10 per cent fluorescein.

RESULTS

2 c.c. 1 per cent acridine orange—Usually faint yellow reaction, but occasionally good yellow reaction.

1 c.c. 1 per cent flavophosphine—Poor yellow reaction.

*This work was done at the Jewish Hospital, Philadelphia, with the aid of the Jewish Hospital Research Fund.

Received for publication, December 16, 1940.

- 2 c.c. 1 per cent flavophosphine—Good yellow reaction.
- 2 c.c. 1 per cent phosphine—Fair yellow reaction.
- 2 c.c. 0.5 per cent acriflavine—Good yellow reaction.
- 2 c.c. 0.4 per cent indigo carmine—No color reaction.
- 2 c.c. riboflavin—Very faint yellow reaction.
- 2 c.c. 1 per cent fluorescein—Very good yellow reaction.
- 1 c.c. 5 per cent fluorescein—Very good yellow reaction.
- 1 c.c. 10 per cent fluorescein—Brilliant yellow reaction (best).

Therefore, fluorescein gave the best color reaction, being the most intense yellow when noted in the eye. Since sodium fluorescein is more soluble than fluorescein, the former was used to make up a 10 per cent solution. Acriflavine appeared to be the next best.

The circulation time test was done in over 70 instances, although the same rabbits were used on successive days or weeks. The same rabbit could even be used about one hour after the test, since much of the dye would disappear from the eye in that time. The circulation time in rabbits averaged between five and six seconds. Occasionally, it would be as low as $4\frac{2}{5}$ seconds or as high as seven seconds.

In rabbits, 2 c.c. of 5 per cent sodium fluorescein injected intravenously gave a slight yellow reaction in the inner margins of the eyelids at the end of eight seconds, using ordinary daylight and no ultraviolet machine. However, the end point was not sharp. Therefore, for this experiment it is advisable to have an ultraviolet machine, a filter suited for fluorescence, and a room that can be made dark by turning off the light switch.

A 1 c.c. tuberculin syringe and a No. 24 gauge needle were used in the rabbits, since this was found to consume less than one-half second for intravenous injection.

The 10 per cent sodium fluorescein solution in distilled water was autoclaved for fifteen minutes, a sample was checked for sterility and toxicity by inoculation into a rabbit, and then used for intravenous injection in human beings. The circulation time was then noted to be $11\frac{1}{2}$ seconds, 12 seconds, etc., in normal people. This was done in seven cases. There were no toxic reactions noted and no change in temperature, pulse rate, and respiration. A 5 c.c. syringe and a No. 21 or 18 gauge needle were used in man, with 4 c.c. of 10 per cent sodium fluorescein injected intravenously. In several additional cases, 3 c.c. of 20 per cent sodium fluorescein was used intravenously and gave even a better color reaction. There were no untoward reactions. By pulling the lower eyelid down and directing the ultraviolet light toward the conjunctiva after the substance was injected intravenously, a sharp yellow end point could be noted.

SUMMARY

A new objective circulation time test is presented, and after using various fluorescent substances, it was found that in rabbits the following technique was best. Using a 1 c.c. tuberculin syringe and a No. 24 gauge needle, 1 c.c. of 10 per cent sodium fluorescein was injected into the marginal vein of the ear. The

stop watch was started, the light was switched off in the room, the ultraviolet light plus filter was directed toward the rabbit's eye, and the stop watch was stopped immediately upon noting a brilliant yellow color in the iris of the eye. Simultaneously, the conjunctiva along the inner margin of the eyelids would become a brilliant yellow.

The average circulation time in rabbits was five to six seconds.

A similar test is being done in human beings, using 4 c.c. of 10 per cent sodium fluorescein or 3 c.c. of 20 per cent sodium fluorescein.

I wish to thank Doctors Follweiler, S. Guttman, I. Wolman, and Miss Spear for their valuable assistance.

CHEMICAL

THE PHOTOMETRIC DETERMINATION OF SUGAR IN BIOLOGICAL FLUIDS BY FERRICYANIDE REDUCTION*

ABRAHAM SAIFER AND FLORENCE VALENSTEIN, JAMAICA, L. I., AND
JAMES P. HUGHES,† NEW YORK, N. Y.

WITH the advent of photometry or "photoelectric colorimetry" into biochemical analysis, numerous papers have been published on the photometric determination of sugar. Yet none of these methods has been so successful from the point of speed, precision, and reproducibility as to aid in supplanting the visual methods used at present. We feel that this paper meets such a need for the routine clinical analysis of sugar in biological fluids.

Photometric methods for sugar are in the main adaptations of existing copper or ferrieyanide methods. Of the copper methods, modifications of the original Folin-Wu¹ have been the most popular. This method has been investigated by Sanford, Sheard, and Osterberg,² and by Fiorentino and Giannettasio.^{3, 4} We have carefully investigated both the Folin-Wu and the Benedict⁵ methods with a view to their possible adaptation to the photoelectric colorimeter. It was found impossible to obtain checks on runs performed from day to day, using the same set of reagents. Accurate results could be obtained only if a sufficient number of standards were run with each unknown, or set of unknowns, to allow for the plotting of a new calibration curve. An inherent advantage of ferrieyanide methods is the greater stability of the reduction product, ferroeyanide, over the reduction products of the copper reagents. Therefore, photometric ferrieyanide methods were then investigated. Hoffman⁶ has described an adaptation of the ferrieyanide fading method of Hawkins and Van Slyke.⁷ The method has been found to give good results which are reproducible from day to day. The disadvantages of the method are: (1) an additional quantitative measurement is required, i.e., the ferrieyanide in addition to the filtrate; (2) the spread is small, being only 30 divisions for a difference of 200 mg. of glucose per 100 c.c.; (3) the method is least sensitive at low sugar values and the most sensitive at high values.

The Folin-Malmros⁸ ferrieyanide colorimetric method has been found to be particularly suited for microsugar methods because of the intense blue colors obtained for small amounts of biological fluids. This method has been adapted for the photoelectric colorimeter by Jourdonais,⁹ using the original procedure

*From the Chemistry Division of the Department of Pathology, Queens General Hospital, Jamaica, L. I.

†Present address: Chemistry Department, College of the City of New York, New York.

Received for publication, April 8, 1941.

except for a longer heating time. This author finds that the colors produced do *not follow Beer's law* and give incomplete recoveries for added amounts of pure glucose. A special correction curve is required to obtain correct results. Marenzi and Villalonga¹⁰ also have applied the Folin method to the photoelectric colorimeter. An advantage of their method is the substitution of lithium and ammonium tartrate in place of gum ghatti in the ferric iron reagent. The method, however, uses sodium cyanide in the alkaline reagent. (The undesirable effects of sodium cyanide will be noted later.) The method has also been investigated by Evelyn,¹¹ who increases the range of readings by leaving out the sodium cyanide from the carbonate reagent and runs his calibration curve in the presence of the tungstic acid solution used for the precipitation. The method still makes use of the ferric iron-gum ghatti reagent which gives variable blanks.

A visual method recently described by Klendshoj and Hubbard¹³ does not use sodium cyanide, and substitutes for the gum ghatti an emulsifying agent (Duponol) which gives negligible blanks, yet stabilizes the Prussian blue solutions over long periods of time.

The last method, with several important modifications, has been adapted by us for purposes of photoelectric colorimetry. For routine sugar analyses the method has been found to give values that compare favorably in precision with the Hagedorn-Jensen¹⁴ procedure and in speed of determination with the original Folin-Wu procedure.

EXPERIMENTAL

A. Reagents.—(1) Ferrieyanide reagent: 0.1 per cent of pure, crystalline, potassium ferrieyanide (prepared free of ferrocyanide according to Folin as given by Peters and Van Slyke¹⁵) was dissolved in a 3 per cent solution of sodium carbonate. The appropriate amount of ferrieyanide was weighed on an analytical balance, made up to volume in a volumetric flask with 3 per cent sodium carbonate solution, and allowed to stand in a dark closet for several days. Any precipitate formed was removed by filtering the solution into a glass-stoppered, amber reagent bottle before using.

(2) Ferric iron reagent: Into a liter beaker weigh 5 Gm. of ferric sulfate (Mallinckrodt—analytical grade) and dissolve with stirring in about 500 ml. of distilled water. (Some difficulty may be encountered in bringing the ferric salt into solution, but HEAT MUST NOT BE USED if reproducible results are desired with each fresh batch of the reagent prepared.) Add slowly 75 ml. of 85 per cent phosphoric acid (reagent grade), stirring constantly. A precipitate or cloud forms, which quickly dissolves with the further addition of the phosphoric acid. An absolutely water-clear solution should now be obtained which is diluted to 1 liter with distilled water. Now add 16 Gm. of "Duponol" P.C. (an emulsifying agent sold by E. I. Du Pont De Nemours and Co., Fine Chemicals Division, New York, N. Y.) in small amounts, stirring constantly until complete solution takes place. Remove all traces of turbidity by allowing the solution to stand in an incubator at 37° C. overnight. Add 5 ml. of concentrated sulfuric acid (reagent grade, sp. gr. 1.84) to repress the hydrolysis of the ferric salt. The solution is now ready for use and will remain clear almost indefinitely if kept at room temperature when not in use.

(3) Tungstic acid* solution for the preparation of the Folin-Wu filtrate: Solution A: 6 ml. of concentrated sulfuric acid (reagent grade, sp. gr. 1.84)—diluted to 2 liters with distilled water in a volumetric flask. Solution B: 111 Gm. of sodium tungstate ($\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$) are dissolved in a liter of solution.

For use, 8 parts of solution A are mixed with 1 part of solution B. This should be prepared fresh at least once weekly.

For whole blood, serum, or plasma: one part of whole blood, etc., is mixed with 9 parts of the tungstic acid mixture. Shake. Allow to stand until the mixture turns chocolate brown, and filter through a Whatman No. 1 or No. 2 filter paper.

(4) Glucose standard solutions: (a) A solution of 100 mg. per 100 c.c. of pure, dry, anhydrous Bureau of Standards glucose was prepared in 0.25 per cent benzoic acid solution. (b) A solution of glucose containing 2 mg. per 100 c.c. was prepared by dilution of standard (a) with 0.25 per cent benzoic acid. 1 ml. is equivalent to 100 mg. of glucose per 100 c.c. (c) A solution of glucose containing 5 mg. per 100 c.c. was prepared as in solution (b). 1 ml. is equivalent to 250 mg. of glucose per 100 c.c. (d) A solution containing 10 mg. per 100 c.c. was prepared as in (b). 1 ml. is equivalent to 500 mg. of glucose per 100 c.c.

B. *Selection of Color Filter.*—The proper color filter was selected from spectrophotometric data, obtained over a range of glucose concentrations varying from 0 mg. to 400 mg. per 100 c.c., by means of a Coleman double monochromator spectrophotometer. Careful study of these data showed that Beer's law does *not* apply for any of the wave lengths studied. The most satisfactory transmission band was found to be in the neighborhood of 520 $m\mu$. Six millimeters of a Sextant Green filter—Corning No. 401 (470 to 580 $m\mu$ transmission limits) were, therefore, used for all photometric determinations in this paper.

C. *Description of Instrument and Accessories.*—The instrument† used was essentially the same as that described by Evelyn¹⁰ with several minor modifications so as to make it more suitable and convenient for the routine clinical analysis.

The diameter of the tube holder was made smaller so that it would accommodate ordinary pyrex test tubes (16 mm. by 150 mm.) instead of the larger soft glass tubes described by Evelyn. The tubes used in these determinations were carefully selected from large batches of pyrex tubes in the manner described by Evelyn¹² and were accurately calibrated for 5 ml. and 10 ml. volumes of solution. The determinations were performed directly in the tubes, and the colors were developed and read in the instrument *without* transfers.

The methods as described can be used without change with any standard photoelectric colorimeter now on the market that will accommodate a 10 ml. volume (or less) of solution. With minor adjustments in the volumes of the sample and the reagents used, the method is readily adaptable to any type of photoelectric instrument. For example, by using two and one-half times the

*Routine determinations for urea nitrogen are performed in this laboratory by adding a concentrated urease solution to the whole blood previous to the protein precipitation. A tungstic acid solution stronger than usual is required to precipitate both the excess urease and the blood proteins in order to obtain water-clear filtrates.

†The instrument was designed and built by Mr. Sidney X. Shore, Radio Engineer of Station WNYF, Fire Department of the City of New York.

quantities of sample and reagents given below, the procedure may be performed in regular Folin-Wu sugar tubes, with a final dilution to the 25 ml. mark. The color may then be read by means of transfer with photoelectric instruments which employ optical cells or ungraduated tubes.

Procedure.—(1) Preparation of the calibration curve: Two-tenths milliliter of a 1:4 dilution* of the tungstic acid mixture described above was pipetted into each of the pyrex photoelectric colorimeter tubes. Known amounts of the glucose standard solutions were then pipetted into the appropriate tubes using calibrated volumetric pipettes. One milliliter of the alkaline ferrieyanide reagent was added with a 5 ml. serologic pipette to each tube. Distilled water was added to bring the total volume to about 4 ml. The tubes were heated in a boiling water bath for eight minutes, and then cooled in running water. Five milliliters of the ferrie iron-Duponol reagent were then added and the contents were mixed. Distilled water was then added up to the 10 ml. calibration mark,†

Fig. 1.—Calibration curve for standard glucose solutions for the colorimetric ferrieyanide method. Corning filter No. 401-6 mm.

and the contents were mixed by inversion. The outside surface of the tubes was carefully washed and wiped dry with gauze or lens paper. The tubes were read in the instrument at various time intervals up to sixty minutes against a reagent blank set at 100 per cent transmission. The data for the thirty-minute interval were plotted on semi-logarithmic graph paper and are shown in Fig. 1. The reagent blank was constant and has a transmission of about 98 per cent against distilled water.

A summation of the data obtained indicates: (a) The curve follows Beer's law only between 100 mg. and 400 mg. per 100 c.c. of glucose with any degree of precision. Therefore, a calibration curve, or a table compiled from such a curve, is a necessity if accurate results are to be obtained. (b) Fluctuations obtained in the galvanometer readings for standard glucose solutions are greatest in values below 100 mg. per 100 c.c., and least in values of more than 100 mg. per

*The reason for the 1:4 dilution of the tungstic acid mixture will be discussed later in the paper.

†If foaming occurs, a wire dipped into caprylic alcohol may be touched to the surface of the solution in order to facilitate dilution to the mark.

100 c.c. (c) Good results can be obtained even for low sugar values if the readings are taken between thirty and forty minutes after the addition of the ferric iron reagent. (d) The checks obtained in the triplicate samples with the same glucose concentrations are excellent.

Readings on all further determinations in this paper were, therefore, made between thirty and forty minutes, and the calibration curve (or a table compiled from such a curve) was used to obtain the correct glucose values.

Analytical Determinations.—Hiller, Linder, and Van Slyke¹⁷ have pointed out that the method of Hagedorn-Jensen can be applied to the determination of sugar in Folin-Wu tungstic acid blood filtrates with good results. If tungstic acid filtrate is used in the Hagedorn-Jensen method (in place of the zinc filtrate) from a theoretical point of view, the method should give results that are in perfect agreement with the colorimetric ferrieyanide method we used. Both methods use a similar reducing reagent, i.e., ferrieyanide in sodium carbonate solution, so that the reaction products formed in each of the two methods is the same. The only REAL difference between the two methods is that the Hagedorn-Jensen method determines the excess ferrieyanide (which requires an additional quantitative measurement) by means of an iodometric titration using starch as the indicator, while our method determines the ferrieyanide formed directly by means of the Prussian blue color using a photoelectric colorimeter. Fujita and Iwatake¹⁸ have found that the Hagedorn-Jensen method does not give strictly proportional reduction values over a wide range of glucose values, and for this reason they advocate the use of their own phosphate buffer. To offset this difficulty, since the original Hagedorn-Jensen was used in these determinations, the colorimetric determinations were always run first. Aliquots of filtrate were then selected so that the Hagedorn-Jensen values would all fall within a very limited range. As an added precaution, a set of blanks and a set of standards were run with each series of Hagedorn-Jensen titrations. With these added precautions, the two methods were found to give strictly comparable results.

(1) *Whole blood determinations:* Tungstic acid filtrate (1:10) of whole blood was prepared in the manner described under the preparation of the reagents. Two-tenths milliliter samples of the 1:10 filtrate or 2 ml. samples of 1:100 filtrate (where more accurate results are desired) were pipetted into the appropriate colorimeter tubes, using calibrated volumetric pipettes. One milliliter of the alkaline ferrieyanide solution was then added, and the rest of the determination was carried out as given in the foregoing procedure. The tubes were read after standing for a thirty-minute interval. These determinations were run in triplicate for the purpose of comparison with the Hagedorn-Jensen procedure. A set of glucose standards was run with each set of unknowns. Recoveries were run on the whole blood samples by pooling many bloods together, so that a large quantity of blood was available. A sample of this pooled blood was taken off for analysis in the manner already described. An accurately weighed quantity of Bureau of Standards glucose was placed in a volumetric flask (100 ml.), the glucose was dissolved in the blood sample, and the solution was diluted to mark with the whole blood. Tungstic acid filtrates of this blood

were then prepared, and the sugar then present was determined. The difference between the two values obtained gave the recovery of pure glucose by this method.

The values obtained by this method for whole blood, their comparison with the Hagedorn-Jensen (also run in triplicate), and the recoveries obtained by this method are given in Table I.

5	1,250	1,220			

(2) *Plasma determinations:* Run as for whole blood. See Table I for the results obtained.

(3) *Serum determinations:* Run as for whole blood. See Table I for results obtained.

(4) *Spinal fluid determinations:* Determinations were performed directly on the spinal fluid samples without protein precipitation. The samples were diluted (1:6) with 0.85 per cent sodium chloride for the Hagedorn-Jensen determinations, and then these samples were diluted (1:10) again (or a total dilution of 1:60) for the colorimetric determinations. Because of the small amounts of material available, no recoveries were run. For routine analysis, 0.5 ml. of a 1:10 dilution of the original fluid may be used. The result obtained from the curve is then divided by 2.5 to obtain the correct glucose value.

The results obtained in these runs and their comparison with the Hagedorn-Jensen method are given in Table I.

(5) *Urine determinations*: The samples were prepared in the manner described in Peters and Van Slyke,¹⁹ using Lloyd's reagent. A rough quantitative test was performed on each urine, and the sample was diluted in such a manner as to give values between 0.1 mg. and 0.2 mg. of sugar for the Hagedorn-Jensen runs, and 0.01 mg. and 0.02 mg. of sugar for the colorimetric determinations. Recoveries were run in the same manner as described under whole blood, using normal (or sugar-free) urine. The blank consisted of 2.0 ml. of a 1:1,000 dilution of this urine.

The results obtained in these runs and their comparison with the Hagedorn-Jensen method are given in Table I.

DISCUSSION

A careful physicochemical study of the reducing action of glucose on ferri-cyanide has been carried out by Wood,²⁰ using potentiometric measurements. We have investigated, by means of the photoelectric photometer, the effect of variations of concentrations of the reagents used in the above procedure (following the criteria laid down by Wood). In general, with one important exception (i.e., the use of sodium cyanide), our findings confirm those of Wood.

The concentrations of glucose used in this method (0 mg. to 0.08 mg. glucose or 0 mg. to 400 mg. per 100 c.c.) were chosen for the following reasons:

(a) A 0.2 ml. aliquot of a 1:10 Folin-Wu filtrate could be easily and accurately measured by means of calibrated mark to mark pipettes.

(b) It is *not* desirable to take readings below 20 per cent transmission, since the instrument is relatively insensitive in that region; i.e., large changes of glucose concentration produce relatively small changes of the transmission readings.

(c) The emulsifying agent (Duponol) can hold only a limited amount of Prussian blue in solution over long periods of time (minimum forty-five minutes). Concentrations of glucose greater than 400 mg. per 100 c.c. cause "cracking" or flocculation of the Prussian blue precipitate in relatively short periods of time.

The amount of potassium ferri-cyanide used in this method has been found to be sufficient to take care of the reducing action between 0.10 mg. and 0.12 mg. of glucose, i.e., 500 mg. to 600 mg. per 100 c.c. However, determinations of fluids with sugar concentrations of more than 400 mg. per 100 c.c. should be repeated, using smaller aliquots of the sample. The effect of the benzoic acid used to preserve the sugar standards caused no noticeable reduction of the ferri-cyanide. In order to duplicate as closely as possible the conditions under which glucose is reduced in a blood filtrate, the average concentration of tungstic acid remaining in blood filtrate after precipitation of the proteins was determined gravimetrically.²¹ This quantity of tungstic acid was then added to the glucose standards. It was noted that the alkalinity of the ferri-cyanide affects the rate and amount of reduction considerably. Experimental results obtained showed that a ferri-cyanide reagent containing 3 Gm. of sodium carbonate per 100 ml. of ferri-cyanide solution (0.1 per cent) gave optimum results. Experimental runs made to find the minimum time of heating showed that at least five minutes was necessary for concentrations of sugar below 400 mg. per 100 c.c. Therefore, a

heating time of eight minutes was selected to give a safe margin of time for the complete reduction of the ferrieyanide by glucose. The use of sodium cyanide, as used in the original Folin reagent, was found to be undesirable, because it reduces the range of the method by one-half, and it also seriously affects the reproducibility of results for the reason that the amount of ferrieyanide produced increases with the time of heating up to about forty-five minutes when it begins to level off.

That precise and reliable results can be obtained by this method is shown by the analytical data given in this paper for the various biological fluids. Results obtained by the photometric method are in close agreement with those of the Hagedorn-Jensen method, and the recoveries obtained for added glucose are excellent. The method, as given here, has been used in this laboratory for routine clinical analysis for more than one year with uniformly excellent results. Blanks, and 100 mg. and 200 mg. per 100 c.c. standard glucose solutions have been run daily for that period, with an average error of about ± 2 per cent. In the course of performing these routine determinations and doing the analytical work of this paper, new batches of each reagent were made up at relatively frequent intervals. We were able to check constantly the points of our original calibration curve.

The method, in addition to being more precise, reliable, and economical of material than the old Folin-Wu procedure proved to be much faster for a large number of sugar determinations. The only quantitative measurement required is that of the 0.2 ml. of the 1:10 Folin-Wu filtrate. The sodium carbonate-ferrieyanide solution is pipetted as one reagent, and all the succeeding operations are performed in the individual pyrex tubes without any transfers. The colors developed are read in these same tubes at the rate of about five a minute.

Some objections to the method may arise from the fact that a long waiting time (thirty minutes) is required to allow for full color development before the colorimeter readings are taken. This would be of particular importance in those laboratories where only a few determinations are performed at one time, or in the case of an emergency determination. For emergency determinations, results of sufficient accuracy may be obtained by taking the readings at a ten or twenty minute-time interval, or if more accurate results are desired, additional calibration curves may be drawn for these time intervals.

In agreement with Somogyi²² we have found that ferrieyanide methods give sugar values that average about 20 mg. per 100 c.c. higher for tungstic acid filtrate than those obtained by the copper methods of Shaffer-Hartmann²³ or Benedict. These copper methods give "true sugar" values in that they are not affected by the nonglucose reducing substances present in the tungstic acid filtrate.

We have confirmed the observations of Hoffman, and of Klendshoj and Hubbard, that the colorimetric ferrieyanide method gives results which are in agreement with those obtained by the old Folin-Wu procedure. The normal values for sugar obtained by this method are practically the same as those given by the old Folin-Wu procedure, i.e., from 85 mg. to 115 mg. per 100 c.c. of blood sugar.

SUMMARY

A photometric ferrieyanide method is described for the rapid, precise determination of sugar in small amounts of biological fluids, e.g., 0.2 ml. of a (1:10) blood filtrate. Careful studies of the factors influencing the reduction of ferrieyanide by glucose were made in order to determine optimum conditions and concentrations of reagents. Negligible and constant blanks were obtained by the substitution of "Duponol" for gum ghatti. Reproducible values for standard solutions were obtained for day to day runs even when new reagents were used. The methods gave results for biological fluids that were in agreement with those obtained by the Hagedorn-Jensen procedure and gave excellent recoveries of added glucose.

THE DETERMINATION OF BLOOD LIPIDS IN BLOOD DYSCRASIAS*

EVANS W. PERNOKIS, M.D., M. R. FREELAND, PH.D., AND IDA KRAUS, PH.D.
CHICAGO, ILL.

THE objects of this paper are to compare the values for total blood plasma lipids in blood dyscrasias obtained from the usual alcohol-ether extracts and from petroleum-ether extracts, and to study the nature of the nonlipid contaminants in these extracts.

Pernokis and Freeland^{1, 2} reported elevated total lipid values obtained gravimetrically from alcohol-ether extracts in cases of blood dyscrasias. Their work was well in progress when Christensen³ and almost simultaneously, Van Slyke and Foleh,⁴ reported that nonlipid contaminants were present in the alcohol-ether extracts and also, to a lesser degree, in the petroleum-ether extracts. They also clearly demonstrated that the bulk of these contaminants were urea and chlorides.

We approached the problem in two ways which will be described in turn. The first method was to compare the total lipid values obtained from alcohol-ether extracts with those obtained from petroleum-ether extracts.

Blood plasma was extracted with the usual alcohol-ether mixture. Aliquots of this extract were carefully evaporated to dryness and weighed. This value appears in Table I as "Total Lipids" under the heading "Alcohol-Ether Extract." This alcohol-ether soluble residue was then extracted five times with 5 c.c. portions of petroleum-ether extract. The combined petroleum-ether extract was then carefully evaporated to dryness and weighed. This value appears in Table I as "Total Lipids" under the heading "Petroleum-Ether Extract."

To obtain the values for "Total N as Urea" in Table I, aliquots of both the alcohol-ether and petroleum-ether extracts were subjected to micro-Kjeldahl analysis. The values obtained for total nitrogen were converted to their equivalents in terms of urea because urea is the form in which practically all of this nitrogen is present. The values for "Corrected Total Lipids" in Table I are the values obtained by subtracting the "urea" values from the "Total Lipids" values.

A comparison of the values for "Corrected Total Lipids," as shown in Table I, reveals that only from 46 to 72 per cent of the materials soluble in the alcohol-ether mixture from cases of myelogenous leucemia are soluble in petroleum-ether.

The second method of approach to the problem was an attempt to determine the composition of the material, which is soluble in the alcohol-ether mixture but insoluble in petroleum-ether extract. The procedure used was to use mixed

*The material for this paper was obtained at the Cook County Hospital, Chicago. The determinations were carried out in Laboratory C of Cook County Hospital and the Laboratories of the Presbyterian Hospital, Chicago.

Received for publication, June 13, 1941.

alcohol-ether extracts from blood dyscrasias. The alcohol-ether mixture was carefully evaporated and the dry residue was weighed. The weight of this alcohol-ether soluble material was 0.1605 Gm. It was then extracted five times with 5 c.c. portions of petroleum ether. The petroleum ether was carefully evaporated. The dry residue weighed 0.0733 Gm. This is only 45.7 per cent of the weight of the alcohol-ether soluble substances. The petroleum-ether insoluble material (0.0872 Gm.) was dissolved in 100 c.c. of distilled water. This aqueous solution was used to determine chlorides as sodium chloride, urea, uric acid, creatinine, and total reducing sugars. The results are shown in Table II.

TABLE I

DIAGNOSIS	ALCOHOL-ETHER EXTRACT			PETROLEUM-ETHER EXTRACT			
	TOTAL LIPIOS (GM.)	TOTAL N AS UREA PER 100 C.C.	CORRECTED TOTAL LIPIOS PLASMA	TOTAL LIPIOS (GM.)	TOTAL N AS UREA PER 100 C.C.	CORRECTED TOTAL LIPIOS PLASMA	% PETROLEUM ETHER SOLUBLE
1. Pernicious anemia	1.270	0.053	1.217	0.856	0.021	0.835	68.6
2. Pernicious anemia	1.153	0.040	1.113	0.680	0.027	0.653	58.6
3. Acute myelogenous leucemia	1.293	0.058	1.235	0.933	0.044	0.889	71.9
4. Chronic myelogenous leucemia	1.400	0.048	1.352	0.666	0.043	0.623	46.0
5. Cholesterolemia	4.733	0.114	4.588	4.460	0.088	4.372	95.4
6. Leucemia cutis	1.400	0.072	1.327	0.800	0.034	0.766	57.7
7. Lymphatic leucemia	1.466	0.050	1.416	Accidentally lost			---
8. Uremia	2.133	0.167	1.966	1.130	0.157	0.973	40.4
9. Lymphatic leucemia	1.353	0.050	1.303	0.633	0.026	0.607	40.5
10. Chronic myelogenous leucemia	1.300	0.077	1.223	0.766	0.028	0.738	60.3

TABLE II

Sodium chloride	53.00 mg. or 60.8 per cent of residue
Uric acid	0.25 mg. or 0.3 per cent of residue
Creatinine	0.42 mg. or 0.5 per cent of residue
Urea	33.00 mg. or 37.8 per cent of residue
Reducing sugars	0.00 mg.
Total accounted for	86.67 mg. or 99.4 per cent of residue
Amount insoluble in petroleum ether	0.0872 Gm.
Amount recovered	0.0867 Gm.
Amount unaccounted for	0.0005 Gm.

The petroleum-ether insoluble contaminants consisted of 60.8 per cent of chlorides calculated as sodium chloride and 37.8 per cent of urea. These two contaminants accounted for 98.6 per cent of the total. Uric acid and creatinine accounted for 0.8 per cent, leaving 0.6 per cent unaccounted for. No reducing sugars were demonstrated to be present.

The petroleum-ether soluble material (0.0733 Gm.) was redissolved in petroleum ether and washed five times with 5 c.c. portions of water. The petroleum-ether was carefully evaporated, and the residue was reweighed. The loss of weight was 0.0087 Gm. of material dissolved in the water. This represents a loss of 11.8 per cent of the total petroleum-ether soluble material. The complete nature of this material has not yet been determined, but some of it is urea and chlorides. The problem is being further investigated.

DISCUSSION

The total corrected petroleum-ether soluble lipid values in two patients with pernicious anemia were 69 and 59 per cent of the values obtained for the alcohol-ether extract. In three patients with myelogenous leucemia, the total corrected petroleum-ether soluble lipid values ranged from 46 to 72 per cent of the values obtained for the alcohol-ether extract. The corrected petroleum-ether extraction values in three persons with lymphatic leucemia were 46 to 58 per cent of the alcohol-ether values. In one patient with uremia the petroleum-ether soluble material showed 49 per cent of the value obtained with the alcohol-ether extraction. The most interesting results were obtained in one person with hypercholesterolemia which showed a very marked increase in the total lipids of the blood with the alcohol-ether extraction method, and continued to show 95 per cent of that value in the petroleum-ether extract. This patient showed a tremendous increase in the fatty acids of the blood, values being as high as 2.758 Gm. Due to the unusual character of the lipids in this blood, the results were checked by three different chemists and found to agree.

CONCLUSION

Total lipid determinations done with the alcohol-ether extraction method show values which are much higher than the values obtained with the petroleum-ether extraction method. The values obtained with the petroleum-ether extraction varied from 46 to 95 per cent, with an average of 60.6 per cent of the total lipid values obtained with the alcohol-ether extraction.

The petroleum-ether insoluble material extracted with the lipids in the alcohol-ether extraction was analyzed and showed to contain 61 per cent of sodium chloride, and 38 per cent of urea. The other 1 per cent was present in the form of uric acid and creatinine. No reducing sugars were found.

Washing the petroleum-ether soluble material five times with distilled water showed a loss of 8 mg. of material by weight, which is 11.8 per cent of the total petroleum-ether soluble material.

The one patient with hypercholesterolemia did not show a marked difference in lipid values with the two methods of extraction.

On the basis of all the total lipid values given for normals, as done by the alcohol-ether extraction method by all the accepted authorities, our values for the blood dyscrasias have been high. Our values in the above series with the petroleum-ether extracts average 60.6 per cent of the values obtained with the alcohol-ether extracts, and are higher than normal.

It is obvious on the basis of the findings of Christensen, and Van Slyke and Folch, whose findings we now confirm, that a new standard of normal total blood lipid values must be determined. We are now investigating this question and we shall report our observations on it later.

MEDICAL ILLUSTRATION

RUBBER CASTS OF MEDICAL SUBJECTS

VIRGINIA WOODLAND, CAROLINE TOWSON, AND CARL DAME CLARKE, PH.D.
BALTIMORE, MD.

WAX formulas have been used for some time for casting lifelike subjects. Although they give a true representation of the subject, they are not as durable as might be desired. By substituting prevulcanized latex for the wax, a permanent cast may be obtained. Such rubber casts have many of the advantages of the wax cast, with few of the disadvantages. Fig. 1A is a photograph of a spleen chosen to illustrate this process. The subject is a poor one, since it was removed from a body that had been preserved for several months. However, it is adequate for this description. A fresh specimen would have been more desirable.

Before starting the actual molding, a cardboard or glass box is made to hold the model. Glass was used for the box seen in Fig. 1B and serves to illustrate better the process. A small amount of plaster is poured into the center of the box. The specimen is placed in the plaster and vibrated to rid the surface of bubbles. By pounding several times on the table near the box, these bubbles will disappear, provided the plaster is in a liquid state. Additional plaster is poured into the box and a brush is used to work the plaster up to the edge of the specimen (Fig. 1C). This edge serves as the line of separation previously determined.

After the plaster is set, it is removed from the box, and the spleen is then dislodged from the set plaster. The edges around the impression of the spleen are trimmed of loose plaster and particles that are likely to break off. This set plaster form constitutes the lower half of the mold. Registration grooves are then cut in each corner, as seen in Fig. 1D. These are necessary to insure a perfect fit of the upper and lower halves. The edges of the lower half are greased with petroleum jelly so that it will separate readily from the upper half which is to be made, as shown in Fig. 1E. Care must be taken to prevent the petroleum jelly from getting on the surface of the plaster created by the spleen. If this happens, the surface ceases to absorb the water from the rubber which is to be poured later. The specimen is then replaced.

The plaster is mixed and the upper half of the mold is made, as shown in Fig. 1F. The molding material is applied with a brush into the crevices on the surface of the spleen. The procedure previously described should be followed to remove any air bubbles that may be present. After the plaster has set, the mold is opened and the specimen is removed. There are now two halves of the mold. Before these are put together for the making of the rubber positive,

 F, The completed cast.

a funnel-shaped opening should be cut at the end that affords the best drainage, as illustrated in Fig. 2A. The two halves are placed together and held securely with wire or large rubber bands (Fig. 2B). Such rubber bands can be cut from an old inner tube and serve well for this purpose. The mold is then allowed to dry thoroughly. This usually takes several days; if gentle heat is applied, only a few hours are required to dry the mold.

Liquid vulcanized latex, which has been mixed with a mineral filler such as zinc oxide, is poured into the mold until it is filled completely (Fig. 2C). The mold is then allowed to set until the desired thickness is built up on the inside. As the dry plaster absorbs the water from the liquid rubber, more rubber is added to keep the mold filled at all times. When the cast has obtained the desired thickness, the excess rubber is poured out. This deposit is developed as a crust next to the plaster mold. The thickness of the crust depends on the dryness of the plaster and the consistency of the rubber-filler mixture. For those persons familiar with casting in terra cotta with clay slips, it should be mentioned that the rubber cast is developed within the plaster mold in a similar manner.

When the desired thickness of the rubber has been built up within the mold and the excess latex has been removed, the cast within the mold is allowed to dry overnight. Gentle heat speeds up this process and at the same time dries the plaster mold, thus making it more suitable for casting a second impression. The mold is then opened and the cast is removed. The part created by the funnel-shaped opening is cut away, as seen in Fig. 2D. Unless a nonmetallie water color, having a base reaction, is added to the liquid rubber before it is poured, the resultant cast will be cream colored. Any material having an acid reaction causes the rubber to coagulate and makes it unfit for use. Furthermore, rubber should not be mixed in bowls or containers made of copper or zinc, since these metals destroy the elasticity of the rubber and prevent it from setting properly. After the cast has set within the mold, it is removed. Any trimming or correction of defects that may be necessary should be done with fine-pointed scissors, a razor blade, or a sharp knife that has been dipped into water. The water causes these instruments to cut the rubber without dragging or leaving any rough spots. Small defects are removed with sandpaper, and the cast is given a coat of white shellac or lacquer to prepare it for coloring.

The transparent oil colors used for photo tinting serve excellently for coloring such casts, as illustrated in Fig. 2E. After the color is dry, the cast is given a coat of dammar varnish to make it resemble more closely the wet fresh specimen.

It is absolutely necessary that the color be dry before applying the varnish. Fig. 2F shows the completed rubber spleen. This may be compared with the original seen in Fig. 1A.

The specimen can be mounted in various ways. A base may be attached to the specimen at the point of the funnel-shaped opening. A thin metal rod is generally forced through this opening and sealed within the cast. The other end of the rod is anchored through a wooden or cast metal base.

The liquid vulcanized latex used for this purpose may be purchased from the General Latex and Chemical Co., Cambridge, Mass.; which firm sells the rubber already mixed with the filler. The latex may also be bought for mixing with any filler for specific purposes. This company is not interested in small orders and refers the prospective buyer to one of its agents who sells the vulcanized latex or one of the mixtures under a trade name at higher prices. In gallon lots the price should not exceed fifty cents a pint. However, it is sold under various trade names for as much as three dollars a pint. The average completed specimen would contain only three or four ounces of rubber. However, as much as two quarts may be necessary to fill the mold in order to get the four ounce deposit. The rubber which is poured from the mold may be used again.

The technical process is slightly different with each specimen that presents its own problems. For example, openings, air vents, and drainage vents must be placed at different points, according to the specimen that is being molded. Therefore, this description will overlap at points and be repeated.

The heart is a more complicated subject. A fresh specimen is easier to work with and gives better results than the preserved specimen used in this case. The wall to confine the plaster is made of cardboard (Fig. 3A). The plaster is poured into this space and worked up to the line of separation which has been determined previously. After the plaster has set and formed half of the mold, the specimen is removed (Fig. 3B). The edges are then trimmed and registration grooves are cut. This is done so that the other half of the mold, which is to be made, will fit perfectly with the first half.

After the registration grooves are cut, the first half of the mold is greased with petroleum jelly (Fig. 3C) to make separation possible. Care must be taken to prevent the petroleum jelly from touching the area to be covered with rubber, since the jelly prevents absorption of the water from the rubber into the plaster.

The specimen is then replaced in the mold, and the other half is made (Fig. 3D) by applying the plaster-water mixture directly to the specimen, thus covering the specimen and the first half of the mold.

In Fig. 3E are shown the two halves of the mold with the specimen in-cased. On one-half of the mold an area is outlined in pencil to form the entrance for a funnel through which the rubber is to be poured (Fig. 3F). Notice that this penciled area extends into two parts of the specimen, one at the base of the heart and the other at the cut section of the descending aorta. This allows the liquid rubber to drain from both parts of the specimen. The penciled area is cut out of the plaster to permit the insertion of the funnel seen in Fig. 4C. These areas also serve to drain the rubber from the mold in creating a hollow cast; therefore, they are cut into areas that are likely to form pockets. Pockets without openings will prevent the rubber from flowing out by gravity.

The two halves of the mold are wired together or held together with large rubber bands cut from sections of old automobile inner tubes (Fig. 4B). After the mold is thoroughly dry, the liquid vulcanized latex is poured through the

opening (Fig. 4C). The mold is then allowed to set until a sufficient thickness is built up by the absorption of the water from the liquid rubber into the mold. If the plaster is thoroughly dry, this takes only a few minutes; if the mold is wet, it may take hours. After a cast of sufficient thickness has been formed, the excess rubber is poured out and the hollow specimen is allowed to set overnight to strengthen the rubber. Gentle heat hastens this process and has a

beneficial effect on both the mold and the cast. When the specimen is thoroughly dry, the mold is opened and the cast is removed (Fig. 4D). This positive impression will probably tear if the mold is opened too soon after the pouring.

The rough edge formed by the seam in the mold is trimmed off with a razor blade and sharp knives (Fig. 4E), which, if dipped into water, glide through

the rubber more easily. Any rough areas remaining may be sandpapered smooth or worked smooth with emery wheels, wire brushes, and polishing devices, after which the specimen is given a coat of shellac.

A.

B.

Fig. 5.—A, The actual preserved heart. B, The rubber cast of the same heart colored to resemble a fresh specimen.

Coloring is then applied to simulate either a fresh or a preserved specimen (Fig. 4F). This is done with transparent oil paints or tempera colors. After completely drying, the specimen is given a coat of dammar varnish to create the glossy effect of a fresh specimen. It is then mounted.

Fig. 5A is a photograph of the actual preserved specimen. Fig. 5B is the rubber cast of the specimen. The slight difference in tonal value is the result of applying more red tints to the rubber cast to obtain the appearance of a fresh specimen.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

SCURVY, Human Experimental, Lund, C. C., and Crandon, J. H. J. A. M. A. 116: 663, 1941.

A vitamin C free diet produced scurvy in one of the authors at the end of five months, and certain symptoms of it were severe at six months.

The ascorbic acid level of the blood plasma fell to zero in forty-two days and that of the white blood cells in one hundred and twenty-two days.

A wound healed well after the patient had been three months on a scorbutic diet but not after six months.

There is no correlation between vitamin C intake and plasma levels, and the incidence of postoperative atelectasis and pneumonia.

Vitamin C deficiency may be a factor in failure of some human wounds to heal.

A dietary history should be taken on all patients who come to major surgery and, if a long-continued marked deficiency of the intake of vitamin C is found, the patient should be given from 1 to 4 Gm. of ascorbic acid daily.

AMEBA, Non-Pathogenic, Clinical Symptoms Associated With So-Called, Rothman, M. M., and Epstein, H. J. J. A. M. A. 116: 694, 1941.

Stool specimens from 406 patients located in and about Philadelphia harbored one or more of the five forms of intestinal amoebas. The most prevalent was *Endolimax nana*; *E. coli* was second.

These organisms, including *Diadamoeba fragilis*, had a causal relationship to their symptoms to the extent of 44.1 per cent.

The most common symptoms were constitutional; i.e., extreme tiredness and weakness. Of local nature were abdominal discomfort and diarrhea.

When a coexisting disease is active, the results to be expected may be only partial; i.e., only those symptoms for which the amoeba is responsible will disappear.

The response to carbarsone therapy is usually within three to five days. When no improvement is noted by the tenth day, one may be fairly certain that the symptoms were not due to the presence of the amoeba.

From a clinical point of view, all forms of amoeba appear to have a pathogenic role. Furthermore, since they may represent a serious public health menace and problem, it is suggested that they should be accepted and treated as such until clinical evidence to the contrary can be proved.

SULFANILAMIDES, Method for Obtaining Rapid Bacterial Growth in Cultures From Patients Under Treatment With, Janeway, C. A. J. A. M. A. 116: 941, 1941.

The authors recommend the addition of para-aminobenzoic acid to a final concentration of 5 mg. per hundred centimeters to all routine culture media. It will make cultures from patients under treatment with the sulfonamide drugs mean what they should—i.e., the presence or absence of viable organisms. By way of caution, it must be noted that the body fluids may frequently be sterilized by sulfonamide therapy and then later become positive again when the patient relapses. During the remission positive cultures could be obtained only from the local focus, and no amount of para-aminobenzoic acid would make the cultures of the body fluids positive.

PROTHROMBIN: Quick's Test Simplified by the Use of a Stable Thromboplastin, Souter, A. W., and Kark, R. Am. J. M. Sc. 200: 603, 1940.

Brains were removed from freshly-killed rabbits, and the larger superficial blood vessels were stripped off after washing with water. The brains were then ground to a paste, spread thinly on a glass plate, and thoroughly dried in an oven at 37° C. The dried residue was scraped off the plate, and about 15 c.c. of saline extract were prepared by adding 30 c.c. of 0.85 per cent sodium chloride solution to 3 Gm. of dried brain, mixing with a glass rod and incubating at 56° C. for fifteen minutes. On centrifuging the mixture at 2,000 r.p.m. for five minutes, a somewhat opalescent supernatant fluid was obtained. About 2 c.c. of this extract were set aside for testing as a control, and the remainder was placed in small serum bottles, 1 c.c. in each. The contents of these bottles were then "lyophilized," and at the completion of the process the evacuated bottles were set aside for storage at room temperature (about 20° C.).

The portion of extract which was kept as a control was tested for thromboplastic activity by using to determine the Quick prothrombin times of a series of dilutions of normal citrated plasma with prothrombin-free plasma prepared by the method of Kark and Lozner, so that the preparations contained 100, 80, 60, 40, 20, and 0 per cent prothrombin.

The technique used in the determination of these prothrombin times was essentially that of Quick. One-tenth cubic centimeter of thromboplastin was pipetted into a tube 10 by 75 mm., and the tube was placed in a constant temperature (37.8° C.) water bath. After a few minutes 0.1 c.c. of plasma was added, and immediately thereafter 0.1 c.c. of 0.277 per cent solution of calcium chloride. A stopwatch was started at the moment of delivery of the calcium chloride solution from the pipette. The tube was agitated gently in the bath for fifteen seconds and then rocked while held in the air until the contents ceased to flow freely. At this point the watch was stopped and the time was taken.

Bottles containing the dry, powdered, "lyophilized" material were opened at intervals of one, two, three, four, and ten weeks after "lyophilization," and the contents were restored to their original volume by the addition of distilled water, when a somewhat opalescent solution was readily obtained. The thromboplastic activity was then determined on each occasion by testing against plasmas containing various percentages of prothrombin. At the same time the results obtained were compared with those given by an extract freshly made up from the original dried rabbit brain substance stored in the icebox at 5° C. The figures for these results are shown in Table I.

TABLE I

QUICK PROTHROMBIN TIME OF MIXTURES OF NORMAL AND PROTHROMBIN-FREE PLASMAS,
USING FRESHLY PREPARED AND LYOPHILIZED THROMBOPLASTINS

	Time in weeks after lyophilization of throm- boplastin at which Quick prothrombin times were observed	Quick prothrombin times of mixtures of normal plasma and prothrombin-free plasma (seconds) Percentage of normal plasma in mixture

STREPTOCOCCUS, Convalescent Serums (Scarlatinal), Platon, E. S., Dwan, P. F., and Hoyt, R. E. *J. A. M. A.* 116: 11, 1941.

The clinical and experimental evidence presented suggests the following points:

1. Erythrogenic toxin, produced in varying amounts by any of Griffith's thirty types of hemolytic streptococci, is important in the pathogenesis of scarlet fever and other streptococcal infections, and its prompt neutralization is desirable.
2. Other toxic products of the hemolytic streptococcus, such as leukocidin, fibrinolysin, and spreading and invasive factors, have received inadequate consideration.
3. The ideal antiserum for treatment of infections due to group A hemolytic streptococci (including scarlet fever) is one which is rich in both group specific and type-specific antibodies and which is homologous.
4. Though commercial scarlet fever antitoxin has merit as a neutralizing agent against erythrogenic toxin, it lacks any antibacterial or anti-invasive properties.
5. Pooled convalescent scarlet fever serum in large doses confers considerable antitoxic immunity and in addition an effective antibacterial immunity.
6. Heterologous serum (horse) may cause reactions which can predispose to bacterial spread.
7. Attempts to increase the antitoxic titers of human convalescent donors have been unsuccessful.
8. Hyperimmunization of convalescent donors with streptococcus vaccines did not result in increased antibacterial activity under the conditions of the authors' experiment.
9. Pooling human sera according to antibody activity and type and administration of this product intravenously offer an immunologically sound basis for the serum treatment of group A streptococcus infections.

TISSUE: A Rapid Method of Staining Fat in Frozen Sections With Osmic Acid, Krafiian, A. *Arch. Path.* 50: 766, 1940.

1. Fix tissue in a 10 per cent solution of formaldehyde for twenty-four hours.
2. Cut frozen sections 10 microns thick.
3. Bring to a boil a 1 per cent aqueous solution of osmic acid in a pyrex test tube and pour the solution into a small Stender dish.
4. Place the section in the hot osmic acid solution and keep it in a paraffin oven at 60° C. for five minutes.
5. Wash in a basin of tap water.
6. Counterstain in 1 per cent aqueous eosin or phloxin for one minute.
7. Wash rapidly in tap water.
8. Transfer the section to a slide and let drain off.
9. Place 3 large drops of glycerin jelly (previously melted in a paraffin oven or a water bath) and cover with a cover slip.

Result: The fat globules are black or gray black; the background is red.

For emergency examination, bring a 10 per cent solution of formaldehyde to boil in a pyrex test tube (60 c.c. capacity); drop a thin piece of biopsy or autopsy material into it, and place the specimen in a hot oven (60° to 65° C.) for ten minutes. Cut thin frozen sections and stain by the method described.

It is not necessary to discard the used osmic acid solution. Pour it back into the stock bottle and use it over and over.

TISSUE, Combined Stain for Fat and Elastic, French, O. *Arch. Path.* 50: 1245, 1940.

Method of Embedding

1. Fix tissues in solution of formaldehyde for twenty-four hours or longer.
2. Wash in running water for five hours.
3. Place in a 5 per cent aqueous solution of gelatin (Knox) at 37° C. for twelve to twenty-four hours.

4. Place in 10 per cent aqueous solution of gelatin at 37° C. for six to twelve hours.
5. Embed in 10 per cent gelatin. Harden in icebox for two to four hours.
6. Before cutting, place individual blocks in solution of formaldehyde for twelve to twenty-four hours (either blocks or sections may be preserved indefinitely in solution of formaldehyde).
7. Cut sections on freezing microtome at 10 microns.
8. Before staining, place sections in formaldehyde for twelve to twenty-four hours.

Method of Staining

1. Rinse section well in distilled water.
2. Dip several times into 70 per cent alcohol.
3. Place in fat and elastic tissue stain, warmed to not more than 45° C. for fifteen minutes.

Formula for stain:

Weigert's elastic tissue stain (ripened)	10 c.c.
Distilled water	2 c.c.
Scarlet red, saturated solution in equal parts of acetone and 70 per cent alcohol	8 c.c.

4. Rinse in 70 per cent alcohol.
5. Rinse in distilled water.
6. Place in Delafield's (or other) hematoxylin for one to two minutes.
7. Rinse in distilled water.
8. Differentiate in 0.5 per cent acid alcohol if desired.
9. Immerse in weak ammonia until the section becomes blue.
10. Rinse in distilled water.
11. Transfer to a slide, drain, and mount in glythrogel. (If desired, 1 per cent aqueous vert lumiere may be used as a counterstain after the hematoxylin, followed by mild decolorization in 60 per cent alcohol.)

DEXTROSE TOLERANCE, Oral and Intravenous, in Cases of Acute (Catarrhal) Jaundice,
Paehman, D. J. Am. J. Dis. Child. 60: 1277, 1940.

The tolerance to dextrose (orally and intravenously administered), the icteric index, and the bilirubin content of the blood were determined serially in 12 children with catarrhal jaundice.

The icteric index closely paralleled the serum bilirubin content of the blood.

Total cholesterol values were normal or below normal in all but 3 patients. The percentage of esters was decreased in 75 per cent of the children.

No correlation was found between the degree of icterus and the type of dextrose tolerance curve obtained.

Decreased tolerance to orally administered dextrose was frequently found when the response to the previous intravenous test had been normal.

When the intravenous test showed a decrease in tolerance, the tolerance to orally administered dextrose was also decreased.

Improvement of a previously decreased tolerance to dextrose (orally or intravenously administered) usually accompanied clinical improvement and a decrease in the degree of icterus.

SUBJECT INDEX

Abstracts are indicated by (Abst.) after the page number; book reviews by (B. Rev.) after the page number.

A

- Abdominal organs, allergy of, 1867
- Absorption bulb to determine oxygen of air, 1376
 - of sulfanilamide, comparative studies of, 371
- Acetate, desoxycorticosterone, effect of, on hypochloremia in pneumonia, 1642
- Acetoacetic acid in urine, quantitative estimation of, 1216
- Acetone, estimation of, clinical application of microdiffusion method for, 878
 - in urine, quantitative estimation of, 1216
- Acetyl- β -methylcholine chloride, administration of, by iontophoresis, 1012
- Acetylcholine in urine, study of, 842
- Acid, hippuric, in urine, 729
- Acid-base balance, effect of sulfanilamide on, 1154
 - in plasma and blood cells of women, 513
 - of blood during toxemias of late pregnancy, 664
- Acid-soluble phosphorus, organic, of red blood cells, 190
- Acidosis, ammonium chloride, 191
 - diabetic, 192
 - of gastroenteritis, 193
- Acridavine in giardia infections, 1468
- Acute edematous pancreatitis, 1901
 - glomerulonephritis, capacity of kidney to concentrate urine in, 1160
- Adenoma, chromophobe pituitary, with Simmonds' disease, 1289
- Adrenal gland, disease of, alteration of glucose tolerance in, 360
 - in experimental hyperthyroidism, epinephrine output from, 981
 - in parathyroid activity, epinephrine secretion from, 1084
- Adrenaline, 25
- Agglutination, cross, methods, technique and comparative values of, 557
 - slide, to determine pathogenicity of staphylococci, 1864 (Abst.)
- Air, oxygen of, in oxygen tent, absorption bulb for determining, 1376
- Alabama, tests for syphilis in, 1790
- Albino rats, pneumococcal infection in, non-traumatizing method of inducing, 1181
- Albumin plasma, in healthy individuals, 1638
- Albumin-globulin ratio of serum, 1553 (Abst.)
- Alcohol in blood and urine, determination of, 399
 - isopropyl, 1788
 - of lung air as index of alcohol in blood, 1527
- Alimentary tract of food-sensitive children, allergic reactions in, 1872
- Allergens, electrophoresis with reference to, 174
 - specific, in hay fever, complement fixation with, 1586
- Allergic diseases, histamine treatment of, 802
 - disorders with histamine and histaminase, 110
 - pneumonia, 1427
 - reactions in organs of monkey, 1870
 - shock tissue, 1874
- Allergy, bacterial, mechanism of, 102
 - food, familial nonreaginic, 1878
 - as predisposing cause of common cold, 757
 - histamine therapy in, 499
 - in relation to purpura, 1105
 - insulin, simulating coronary occlusion, 1090
 - of abdominal organs, 1867
 - respiratory, fungi in, 1593
- Alternating current photoelectric colorimeter, 416
- Alveolar and venous airs, alcohol in, 1532
- American College of Physicians, 1709 (B. Rev.)
- Amines, 25
- 4-Amino-2-methyl-1-naphthol in hypoprothrombinemia, 818
- p-Aminobenzoic acid, inhibition of action of sulfanilamide by, 917 (Abst.)
- Ammonia in distillates, determination of, 1845
- Ammonium chloride acidosis, 191
 - gluconate and gluconic acid in animals and man, 1574
- Amniotic fluid pneumonia, chronic, 772
- Amoeba, nonpathogenic, 1989 (Abst.)
- Amylase, estimation of, 1904
 - test, serum, 1901
- Anacrobies, sporulating, isolation of, composition tubes as substitute for glass in, 1957
- Anaerobic drawing and sampling of blood for gas analysis, 1685
 - pneumococcus, 307
- Analgesics, 135
- Analysis, gas, blood for, anaerobic drawing and sampling of, 1685
- Anaphylactic phenomena, inhibitory effect of fever on, 125
 - shock in guinea pigs, inhibition of, 128

- Pyruvate, blood, in vitamin B₁₂ deficiency, 1314
- Q
- Quantitation, colorimetric, by Oesting's technique, 881
- Quantitative estimation of acetone and acetoacetic acid in urine, 1216
- of serum globulin in hyperglobulinemia, 1211
- "Quellung" reaction, pneumococcus typing by, improved technique for, 1672
- Quick's test simplified by use of stable thromboplastin, 1990 (Abst.)
- R
- Rabbit, ear vein of, aid in injection of, 1956
- heart blood samples, blood sugar values from, 725
- in vivo study in, 1111
- 1461
- 1129
- experimental lesions in,
- subcutaneous administration of protamine to, 1416
- Rack for syringe outfit in use, 388
- Radioactive phosphorus in rodents, distribution of doses of, 1014
- Ragweed pollen extracts, development of sensitivity to, in guinea pig, 1603
- Rat, albino, pneumococcal infection in, non-traumatizing method of inducing, 1181
- cage for metabolism studies, 1849
- pneumonia in, treatment of, 1284
- white, artificial insemination of, 1361
- Ratio, macronucleolus and nucleonucleolar, of cancer to histologic grading, 1612
- of free to total phenolphthalein in urine, 1148
- Raynaud's disease, capillary studies in, 1729
- Reaction, formol-gel, 1211
- phytotoxic, of some blood sera, 597
- precipitin, in rheumatoid arthritis, 464
- "Quellung," improved technique for pneumococcus typing by, 1672
- Takata-Ara, in cerebrospinal fluid, 1079
- Weilmann's coagulation, simple modification of, 1795
- Rectum, carcinoma of, 1707 (Abst.)
- Red blood cell diameter, measurement of, by diffractometer, 696
- cells in acidotic states, acid-soluble phosphorus of, 190
- Reduced blood, undiluted, hemoglobin estimation with, 1823
- Refrigeration, patients with cancer subjected to, 443
- Regional diagnosis in lesions of brain and spinal cord, compendium of, 756 (B. Rev.)
- Renal aspects of experimental and clinical hypertension, 1713
- function, 1864 (Abst.)
- in hypertension, 1718
- phenolsulphonophthalein test of, 587
- lesion associated with jaundice, 914 (Abst.)
- with sulfapyridine therapy, 436 (Abst.)
- pathology, clearance tests in relation to, 796
- pressor system, 1716
- crystalline (Abst.)
- 93
- cancer
- system, 1558 (Abst.)
- system, its physiology and pathology, 89
- Rheumatoid arthritis, glucose tolerance curves in, effect of diet on, 675
- gold salts in treatment of, toxic reactions with, 1629
- sodium thiomalate, in, 1750
- on, effect of, 1274
- indoluria in, 1939
- precipitin reactions in, 464
- treatment of, 1918
- Rhinitis, vasomotor, 803
- Riboflavin, 21
- Rickettsial infection, 245
- Infections, bacillary and, 1401 (B. Rev.)

- Rodents, radioactive phosphorus in, 1014
 Rodilone, toxic effects of, in anoxia, 479
 Roentgen sickness, 39
 Rouleaux, sedimentation rate of, 545
 Rubber casts of medical subjects, 1981
 Russell viper venom, prothrombin estimation using, 1366
- S
- Sabin agglutination test, 1555 (Abst.)
 as control of sulfapyridine treatment of pneumonia, 752 (Abst.)
 Saccharomyces fragilis Jorgensen, 294
 Saliva, iodine content of, in normal persons, 1942
 Salmine, subcutaneous administration of, to rabbits and mice, 1416
 Salts, gold, in treatment of rheumatoid arthritis, toxic reactions with, 1629
 Scarlatinal serums, 1991 (Abst.)
 Schick reaction, 1232 (Abst.)
 Scientific illustrations, sharpness considerations in making, 1388
 Scurvy, human experimental, 1989 (Abst.)
 Sediment following pyridium administration in urinary infections, 1768
 Sedimentation curves, blood, mechanically recording, 1945
 rate in healthy girls, 987
 in patients with low-grade chronic illness, 621
 technique for, 542
 Westergren, technique, 1516
 Semisolid double sugar medium for identification of colon-typhoid group, 1951
 Sensitivity to egg albumen and ragweed pollen extracts in guinea pig, effect of carbon tetrachloride and thyroxine on, 1603
 Septicemia, staphylococcic, 1232 (Abst.)
 Sera, blood, cystine content of hydrolysates of, 1635
 phytotoxic reactions of, 597
 Serologic reactions, false positive, for syphilis in infectious mononucleosis, 1439
 tests for syphilis, method for intrastate evaluation of, 1789
 transient positive, 791
 Serology of syphilis, 139
 Serum, albumin-globulin ratio of, 1553 (Abst.)
 amylase test, 1901
 bacteriostatic properties of, in patients with rheumatoid arthritis, effect of gold sodium thiomalate on, 1274
 calcium, blood, in negro, 1644
 cholesterol studies following acetyl- β -methylcholine chloride by iontophoresis, 1012
 electrophoresis with reference to, 174
 globulin in hyperglobulinemia, 1211
 human, effect of, on blood antitoxin titer and Schick reaction, 1232 (Abst.)
 iodine absorption by, of epileptic patients, on bromide therapy, 836
 content of, 365
 lipase, 1231 (Abst.)
 protein, application to, 179
 determination of, 1046
 rabbit, antipneumococcic, 1461
 in type I pneumococcus infection of albino rats, 1284
 Sharpness considerations in making scientific illustrations, 1388
 Shaving brushes, anthrax in, 1032
 Shock, circulatory failure of capillary origin, 751 (Abst.)
 pathologic physiology of, 121
 Short wave therapy, foundations of, 1400 (B. Rev.)
 Schwartzman phenomenon, effect of histaminase on, 1432
 Sicca hemometer, 1824
 Sickle-cell anemia, liver extract in, 1470
 Silica, pharmacology of, 774
 Silicic acid, fatal intravenous doses of, 774
 Silver anniversary number, 1
 Simmonds' disease, chromophobe pituitary adenoma with, 1289
 Skin, human, light reflection from, photographic aspect of, 1852
 Slide technique, 557
 Slides, lantern, 1224
 Smears and sections of aspirated sternal marrow, method for preparing, 1784
 vaginal, staining, 1200
 Smegma bacillus, 1705 (Abst.)
 Smoke, cigarette, absorption of nicotine from, 1322
 Sodium chloride crystallization by cerebrospinal fluid, 483
 studies in arterial hypertension, 344
 sulfapyridine, intramuscular administration of, 314
 use of, by hypodermoclysis, 594 (Abst.)
 urinary, volumetric determination of, 889
 Solution and diazotization of bilirubin in chloroform, 1206
 Specific gravity apparatus, inexpensive, 1959
 of blood and body fluids, 1370
 of body fluids, method for determining, 564
 of stools, 1775
 studies, blood, 1934
 determining blood volume changes by, 1545
 Sphygmoscope, student, 1192
 Spinal cord and brain, device for fixing, in one piece, 1809
 fluid, chloride concentrations in, 535
 colloidal carbon flocculation test in, diagnostic value of, 1349
 Spirochetal infection, 246
 Spirocheticides, 137
 Splanchnicotomy, bilateral, in dogs, depressor effect of potassium sulfocyanate before and after, 658
 Spleen, congenital absence of, 772
 tumors of, 630
 Splenic factor in thrombocytopenic purpura, 489
 Spontaneous hypoglycemia, diet in, 828
 Sporulating anaerobes, isolation of, 1957
 Sputum, aspiration of, 1396 (Abst.)
 isolation of fungi from, 1195
 Stain for fat and elastic tissue, combined, 1991 (Abst.)
 Gram modification of, 1518
 Staining blood smears in determining opsonocytaphagic indices, 1811
 gram-positive organisms in frozen sections, 1076 (Abst.)
 jars, turntable for, 562
 method for hemosiderin pigment in heart-failure cells, 700
 vaginal smears, 1200
 Stand for aseptic operations with Horsley-Clarke's stereotaxic instrument, 1657
 Standardization of certain factors in cutaneous "venostasis" bleeding time technique, 1812
 Standards, elimination of, in determination of whole blood specific gravity by falling-drop technique, 1681
 Staphylococci, coagulase test for, 1864 (Abst.)
 effect of sulfapyridine and sulfanilamide on, 1756
 pathogenicity of, use of slide agglutination to determine, 1865 (Abst.)
 septicemia, 1232 (Abst.)
 Staphylococcus toxin, effect of sulfapyridine on, 1111
 Stereotaxic instrument, Horsley-Clarke's, stand for aseptic operations with, 1657
 Sterility, male, testicular biopsy in, 1708 (Abst.)
 menstrual disorders and, diagnosis and treatment of, 1709 (B. Rev.)
 Sternal marrow, aspirated, method for preparing smears and sections of, 1784
 Stools, composition of, effect of bran on, 1774
 human blood and human protein in, immunologic test for, 1030
 infective, in infantile paralysis, 1906
 Straw, cellophane, used as an ink-writing pointer in kymographic work, 1650
 Streptococci, human hemolytic, 435 (Abst.)
 Streptococcus, convalescent serums, scarlatinal, 1991 (Abst.)
 Stroma in polycythemia and beef embryo, 1492
 Strongyloides stercoralis infestation, case of, 1608
 Subcutaneous administration of protamine (salmine) to rabbits and mice, effect of, 1416
 Sugar, blood, normal values in children, 1864 (Abst.)
 parotid gland on, influence of, 1009

Tissue—Cont'd

- Hamdi's preserving solution, 915 (Abst.)
 macrophage, 91
 staining fat in frozen sections with osmic acid, 1991 (Abst.)
 within, method of, 1554 (Abst.)
 subjected to subcritical temperatures, pathologic changes in, 753 (Abst.)
 Tobacco, cutaneous manifestation from, 1399 (Abst.)
 Toluol, anti-M and anti-N agglutinins with, preservation of, 866
 Torula infection of central nervous system, 299
 meningitis, 258
 Toxemias of late pregnancy, blood during, 664
 Toxic effects of sulfanilamide, sulfapyridine, and rodlone in anoxia, 479
 hepatitis due to sulfanilamide, 785
 reactions with gold salts in treatment of rheumatoid arthritis, 1629
 Toxin, staphylococcus, effect of sulfapyridine on, 1111
 Transfusion, blood "banks" in, 82
 of preserved blood, leucocyte count following, 1911
 Trichinella spiralis, 917 (Abst.)
 Trichinosis, incidence of, 753 (Abst.)
 Tropical diseases, Manson's, 439 (B. Rev.)
 Trypanocides, 136
 Tube for tattoo machines, 1525
 hematocrit, filling pipette, 1348
 Tubercle bacilli, demonstration of, 1396 (Abst.)
 differentiated from smegma bacillus, 1705 (Abst.)
 effect of egg oil on, 1073 (Abst.)
 Tuberculin reaction, instability of, 1397 (Abst.)
 tests, routine, significant errors in, 1652
 Tuberculosis, 287
 pulmonary, monilia simulating, 624
 Tubes and bottles, culture, bacteriologic, cotton-plug wrapping machine for, 1040
 composition, as substitute for glass, 1957
 intubation, for insufflation anesthesia in dogs, 854
 Tumor, artificial, in brains of cats, production of, 1778
 asphyxia of, combinations of chemicals in, 1120
 cell, of frontal bone, 319
 giant cell, of bone, 1705 (Abst.)
 of spleen, primary malignant, 630
 of vulva, 591 (Abst.)
 Turntable for staining jars, 562
 Typhoid carriers, 1072 (Abst.)
 fever, bone marrow in, bacteriologic culture of, 1024
 vaccine, protective antibodies produced by, 1583

U

- Ulcerative colitis, relation of nasopharynx to, 1925
 Urea determination for routine blood chemistry, 405
 in blood and urine, 437 (Abst.)
 nitrogen of blood, microdetermination of, 874
 Urinary androgens, extraction of, 881
 infections, organized sediment following pyridium administration in, 1768
 porphyrin before and after hydrolysis, 1676
 sodium, volumetric determination of, 889
 tract, chemotherapy in nonspecific infections of, 1863 (Abst.)
 Urine, acetone and acetoacetic acid in, 1216
 acetylcholine in, study of, 842
 alcohol in, determination of, 399
 ascorbic acid in, determination of, 1542
 bilirubin in, comparison of tests for, 1234 (Abst.)
 photometric determination of, 423
 calcium in, determination of, 585
 chemical constituents, 214
 concentrate, in acute glomerulonephritis, capacity of kidney to, 1160
 control of urinary reaction, 752 (Abst.)
 creatine in, conversion of creatinine into, 1673
 formation of, 751 (Abst.)
 hippuric acid in, determination of, 1629
 iodine content of, in normal persons, 1942

Urine—Cont'd

- isolation of paratyphoid, dysentery, and typhoid from, 592 (Abst.)
 magnesium content of, 521
 nicotinic acid in, determination of, 1042
 sugar, estimation of, 1220
 sulfathiazole in, 1706 (Abst.)
 urea in, 437 (Abst.)
 Urticaria, treatment of, 501
 Uterotubal insufflation, experimental, 1447
 in rabbit, experimental, 1129
- V
- Vaccine, autogenous, administration of, to persons with low-grade chronic illness, 1453
 typhoid, protective antibodies produced by, 1583
 Vaginal smears, staining, 1200
 Variations in composition of gastric juice, 682
 Vasodilators, 135
 Vasomotor rhinitis, 802
 Vein, ear, of rabbit, aid in injection of, 1956
 Velocity, blood, determination of, by lobeline, 766
 Venom, Russell viper, prothrombin estimation using, 1366
 "Venostasis" bleeding time technique, cutaneous, 1812
 Venous blood cultures, 382
 Ventricular failure, left, due to essential hypertension, 1891
 Vertical illuminator for student microscope, 868
 Vessel for measurement of pH and oxidation-reduction potential of bacterial cultures, 1513
 Virulence of Corynebacteria, 553
 testing, use of single guinea pig for, 863
 Virus infections, 244
 Viruses, 250
 Visscher-Bowman chemical test for pregnancy, 1374
 Vitamin A, 23
 B, deficiency, blood pyruvate in, 1314
 C, effect of, on workers exposed to lead dust, 1478
 D, line test for, osteotropic dyes in, 714
 E, 595 (B. Rev.)
 K activity of 2-methyl-1, 4-naphthoquinone and 4-amino-2-naphthol in hypoprothrombinemia, 818
 administered to mothers in labor, effect on newborn of, 1305
 nutrition, determination of, 45
 Vitamins and drugs with cell catalysts, interaction of, 20
 Volume, blood, and extracellular fluid, in infants and children, 1708 (Abst.)
 cell, of blood, measurement of, by Evans blue dye method, 1829
 changes, blood, method for determining, by specific gravity studies, 1545
 organized sediment, technique for study of, 1768
 plasma, concentration after severe hemorrhage, 1144
 Volumetric determination of urinary sodium, 889
 Vulva, granulomas of, 434 (Abst.)
 tumors of, 591 (Abst.)

W

- Water concentration of blood during toxemias of late pregnancy, 664
 Weil's disease in Hawaii, 750 (Abst.)
 Weltmann's coagulation reaction, simple modification of, 1795
 Westergren sedimentation rate technique, 1516
 Wild plants, edible, 756 (B. Rev.)
 Woldman test, influence of phenolphthalein on, 1148
 Wrapping machine, cotton-plug, for bacteriologic culture tubes and bottles, 1040

X-ray studies, 45

Library
 extract medium, dextrose, for isolation of fungi from sputum, 1195
